Contents

Instead of Introduction

This collection is about ideas, and it is not about theory. An idea might feel more comfortable in a suitable theory, but it has its own live and history and can speak for itself — I hope you will hear it.

I am collecting these problems for fun, but they might be used to improve the problem solving skills in geometry. Every problem has a short elegant solution — this gives a hint which was not available when it was solved for the first time.

How to read it. Open at a random chapter, make sure you like the practice problem — if yes try to solve a random problem in the chapter. A semisolution is given in the end of the chapter, but you should to think before reading it, otherwise it might not help.

Acknowledgments. I want to thank everyone who helped me; here is an incomplete list: Stephanie Alexander, Christopher Croke, Bogdan Georgiev, Jouni Luukkainen, Alexander Lytchak, Rostislav Matveyev, Peter Petersen, Idzhad Sabitov, Serge Tabachnikov.

This collection is partly inspired by connoisseur's collection of puzzles by Peter Winkler [see 1]. Number of problems were suggested on math*overflow* [see 2].

Some problems are marked by $\circ$, $*$, $+$ or $\sharp$.

$\circ$ — easy problem;

$*$ — the solution requires at least two ideas;

$+$ — the solution requires knowledge of a theorem;

$\sharp$ — there are interesting solutions based on different ideas.

Chapter 1

Curves

Recall that a *curve* is a continuous map from a real interval into a space (for example, Euclidean plane) and a *closed curve* is a continuous map defined on a circle. If the map is injective then the curve is called *simple*.

We assume that the reader is familiar with related definitions including length of curve and its curvature. The necessary material is covered in the first couple of lectures of a standard introduction to differential geometry, see [3, §26–27] or [4, Chapter 1].

We give a practice problem with a solution — after that you are on your own.

Spiral

The following problem states that if you drive on the plane and turn the steering wheel to the right all the time, then you will not be able to come back to the same place.

Assume γ is a smooth regular plane curve with strictly monotonic curvature. Show that γ has no self-intersections.

Semiolution. The trick is to show that the osculating circles of γ are nested.

Without loss of generality we may assume that the curve is parametrized by its length and its curvature decreases.

Let $z(t)$ be the center of osculating circle at $\gamma(t)$ and $r(t)$ is its radius. Note that

$$z(t) = \gamma(t) + \tfrac{\gamma''(t)}{|\gamma''(t)|^2}, \qquad\qquad r(t) = \tfrac{1}{|\gamma''(t)|}.$$

Straightforward calculations show that

$$(*) \qquad |z'(t)| \leqslant r'(t).$$

Dentote by D_t the osculating disc of γ at $\gamma(t)$; it has center at $z(t)$ and radius $r(t)$. By $(*)$,

$$D_{t_1} \supset D_{t_0} \quad \text{for} \quad t_1 > t_0.$$

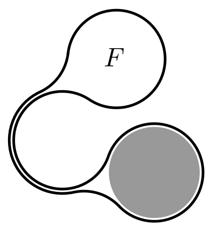
Hence the result follows. □

This problem was considered by Peter Tait in [5] and later rediscovered by Adolf Kneser in [6]; see also [7].

It is instructive to check that 3-dimensional analog does not hold; that is, there are self-intersecting smooth regular space curves with strictly monotonic curvature.

Note that if the curve $\gamma(t)$ is defined for $t \in [0, \infty)$ and the curvature of converges to ∞ as $t \to \infty$, then the problem implies the convergence of $\gamma(t)$ as $t \to \infty$. The latter could be considered as a continuous analog of the Leibniz's test for alternating series.

The moon in the puddle



A smooth closed simple plane curve with curvature less than 1 *bounds a figure* F. *Prove that* F *contains a disc of radius* 1.

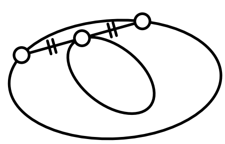
A spring in a tin

Let α *be a closed smooth immersed curve inside a unit disc. Prove that the average absolute curvature of* α *is at least* 1, *with equality if and only if* α *is the unit circle possibly traversed more than once.*

A curve in a sphere

Show that if a closed curve on the unit sphere intersects every equator then it has length at least $2\cdot\pi$.

Oval in oval



Consider two closed smooth strictly convex planar curves, one inside the other. Show that there is a chord of the outer curve, which is tangent to the inner curve at its midpoint.

Capture a sphere in a knot*

The following formulation use the notion of smooth isotopy of knots; that is, one parameter of embeddings

$$f_t\colon \mathbb{S}^1 \to \mathbb{R}^3, \quad t \in [0,1]$$

such that the map $[0,1] \times \mathbb{S}^1 \to \mathbb{R}^3$ is smooth.

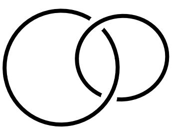
Show that one can not capture a sphere in a knot.

More precisely, let B be the closed unit ball in $\mathbb{R}^3$ and $f\colon \mathbb{S}^1 \to \mathbb{R}^3 \backslash B$ be a knot. Show that there is a smooth isotopy

$$f_t\colon \mathbb{S}^1 \to \mathbb{R}^3 \backslash B, \quad t \in [0,1],$$

such that $f_0 = f$, the length of f_t does not increase in t and $f_1(\mathbb{S}^1)$ can be separated from B by a plane.

Linked circles



Suppose that two linked simple closed curves in $\mathbb{R}^3$ lie at a distance at least 1 from each other. Show that the length of each curve is at least $2{\cdot}\pi$.

Surrounded area

Consider two simple closed plane curves $\gamma_1, \gamma_2\colon \mathbb{S}^1 \to \mathbb{R}^2$. Assume

$$|\gamma_1(v) - \gamma_1(w)| \leqslant |\gamma_2(v) - \gamma_2(w)|$$

for any $v, w \in \mathbb{S}^1$. Show that the area surrounded by γ_1 does not exceed the area surrounded by γ_2.

Crooked circle

Construct a bounded set in $\mathbb{R}^2$ homeomorphic to an open disc such that its boundary contains no simple curves.

Rectifiable curve

For the following problem we need the notion of *Hausdorff measure*. Fix a compact set $X \subset \mathbb{R}^2$ and $\alpha > 0$. Given $\delta > 0$ consider the value

$$h(\delta) = \inf \left\{ \sum_i (\operatorname{diam} X_i)^\alpha \right\}$$

where the infimum is taken for all finite coverings $\{X_i\}$ of X such that $\operatorname{diam} X_i < \delta$ for each i.

Note that the function $\delta \mapsto h(\delta)$ is not decreasing in δ. In particular, $h(\delta) \to h$ as $\delta \to 0$ for some (possibly infinite) value h. This value h is called α-dimensional Hausdorff measure of X and denoted as $\mathcal{H}_\alpha(X)$.

Let $X \subset \mathbb{R}^2$ be a compact connected set with finite 1-dimensional Hausdorff measure. Show that there is a rectifiable curve which pass thru all the points in X.

Typical convex curves

Show that for most *of the convex closed curves in the plane have vanishing curvature at every point where it is defined.*

We need to explain the meaning of word "most" in the formulation; it use *Hausdorff distance* and *G-delta sets.*

The Hausdorff distance $|A - B|_H$ between two closed bounded sets A and B in the plane is defined as the infimum of positive numbers r such that r-neighborhood of A contains B and r-neighborhood of B contains A.

In particular we can equip the space of all closed plane curves with Hausdorff metric. The obtained metric space is locally compact. The latter follows from the *selection theorem* [see §18 in 8], which states the closed subsets of closed bounded set in the plane form a comact set with respect to Hausdorff metric.

G-delta set in a metric space X is defined as countable intersection of open sets. According to *Baire category theorem*, in locally compact metric spaces X, any intersection of countable collection of dense open set has to be dense. (The same holds if X is as complete, but we do not need it.)

In particular, in X, the intersection of a finite or countable collection of G-delta dense sets is also G-delta dense. The later means that G-delta dense sets contains *most* of X. This is the meaning of the word *most* used in the problem.

Semisolutions

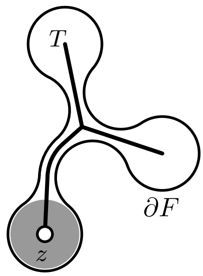
The moon in the puddle. In the proof we will use *cut locus* of F with respect to its boundary[1]; it will be further denoted as T. The

[1] Also called *medial axis*.

cut locus can be defined as the closure of the set of points $x \in F$ such that there are two or more points in ∂F which minimize distance to x.

For each point $x \in T$, consider the subset $X \subset \partial F$ which lies on the minimal distance from x. If X is not connected then we say that x is a *cut point*; equivalently it means that for any sufficiently small neighborhood $U \ni x$, the complement $U \backslash T$ has at least two connected components. If X is connected then we say that x is a *focal point*; equivalently it means that the osculating circle to ∂F at any point of X centered at x.

The trick is to show that T contains a focal point, say z. Since ∂F has curvature of at most 1, the radius of any osculating circle has radius at lest 1. Hence z lies on the distance at least 1 from ∂F and the statement will follow.



Note that after a small perturbation of ∂F we may assume that T is a graph embedded in F with finite number of edges.

Note that T is a deformation retract of F. The retraction $F \to T$ can be obtained the following way: (1) given a point $x \in F \setminus T$, consider the (necessarily unique) point $\hat{x} \in \partial F$ which minimize the distance $|x - \hat{x}|$ and (2) move x along the extension of the line segment $[\hat{x}x]$ behind x until it hits T.

In particular, T is a tree. Therefore T has an end vertex say z. The point z is focal since there is arbitrary small neighborhood U of z such that the complement $U \backslash T$ is connected. $\square$

The problem was discussed by German Pestov and Vladimir Ionin in [9]. Another solution via curve shortening flow was given by Konstantin Pankrashkin in [10]. The statement still holds if the curve fails to be smooth at one point. A spherical version of the later statement was used by Dmitri Panov and me in [11].

The 3-dimensional analog of this statement does not hold. Namely, there is a smooth embedding $\mathbb{S}^2 \hookrightarrow \mathbb{R}^3$ with all the principle curvatures between -1 and 1 such that it does not surround a ball of radius 1. Such example can be obtained by fattening a nontrivial contractible 2-complex in $\mathbb{R}^3$ [the Bing's house constructed in 12, will do the job]. This problem is discussed by Vladimir Lagunov in [13] and it was generalized to Riemannian manifolds with boundary by Stephanie Alexander and Richard Bishop [see 14].

A similar argument shows that for any Riemannian metric g on the 2-sphere $\mathbb{S}^2$ and any point $p \in (\mathbb{S}^2, g)$ there is a minimizing geodesic $[pq]$ with conjugate ends. On the other hand, for $(\mathbb{S}^3, g)$ this is not true.

A related examples discussed after the hint for “Almost flat manifold”, page 47.

A spring in a tin. To solve this problem, you should imagine that you travel on a train along the curve $\alpha(t)$ and watch the position of the center of the disc in the frame of your wagon.

Denote by ℓ the length of α. Equip the plane with complex coordinates so that 0 is the center of the unit disc. We can assume that α equipped with ℓ-periodic parametrization by length.

Consider the curve $\beta(t)=t-\frac{\alpha(t)}{\alpha'(t)}$. Note that

$$\beta(t+\ell)=\beta(t)+\ell$$

for any t. In particular

$$\mathrm{length}(\beta|_{[0,\ell]})\geqslant|\beta(\ell)-\beta(0)|=\ell.$$

Note that

$$\begin{aligned}|\beta'(t)|&=|\tfrac{\alpha(t)\cdot\alpha''(t)}{\alpha'(t)^2}|\leqslant\\&\leqslant|\alpha''(t)|.\end{aligned}$$

Since $|\alpha''(t)|$ is the curvature of α at t, we get the result. □

The statement was originally proved by István Fáry in [15]; number of different proofs are discussed by Serge Tabachnikov in [16], see also [19.5 in 17].

If instead of a disc, we have a region bounded by closed convex curve γ, then it is still true that the average curvature of α is at least as big as average curvature of γ. The proof was given by Jeffrey Lagarias and Thomas Richardson in [18], see also [19].

A curve in a sphere. Let us present two solutions. We assume that α is a closed curve in $\mathbb{S}^2$ of length $2{\cdot}\ell$ which intersects each equator.

A solution with the Crofton formula. Given a unit vector u denote by e_u the equator with pole at u. Let $k(u)$ the number of intersections of the α and e_u.

Note that for almost all $u\in\mathbb{S}^2$, the value $k(u)$ is even or infinite. Since each equator intersects α, we get $k(u)\geqslant 2$ for almost all u.

Then we get

$$\begin{aligned}2{\cdot}\ell&=\tfrac14{\cdot}\int\limits_{\mathbb{S}^2}k(u){\cdot}\,d_u\,\mathrm{area}\geqslant\\&\geqslant\tfrac12{\cdot}\,\mathrm{area}\,\mathbb{S}^2=\\&=2{\cdot}\pi.\end{aligned}$$

The first identity above is called *Crofton formula*. Prove this formula first for a curve formed by one geodesic segment, summing up we get it for broken lines and by approximation it holds for all curves. □

A solution by symmetry. Let $\check\alpha$ be a sub-arc of α of length ℓ, with endpoints p and q. Let z be the midpoint of a minimizing geodesic $[pq]$ in $\mathbb{S}^2$.

Let r be a point of intersection of α with the equator with pole at z. Without loss of generality we may assume that $r \in \check\alpha$.

The arc $\check\alpha$ together with its reflection in the point z forms a closed curve of length $2{\cdot}\ell$ that passes thru r and its antipodal point r^*. Therefore

$$\ell = \operatorname{length}\check\alpha \geqslant |r - r^*|_{\mathbb{S}^2} = \pi.$$

Here $|r - r^*|_{\mathbb{S}^2}$ denotes the angle metric in the sphere $\mathbb{S}^2$. □

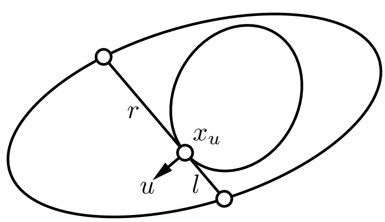
The problem was suggested by Nikolai Nadirashvili. It is nearly equivalent to the following:

Show that total curvature of any closed smooth regular space curve is at least $2{\cdot}\pi$.

A way more advanced problem is to show that any embedded circle of total curvature at most $4{\cdot}\pi$ is unknot. It was solved independently by István Fáry [in 20] and John Milnor [in 21]. Later many interesting generalizations and refinements were found including a generalization to singular spaces by Stephanie Alexander and Richard Bishop [in 22] and the theorem on embedded minimal disc proved by Tobias Ekholm, Brian White and Daniel Wienholtz [in 23].

Oval in oval. Choose the a chord which minimizes (or maximizes) the ratio, in which it divides the bigger oval.

If the chord is not divided into equal parts, then you can rotate it slightly to decrease the ratio. Hence the problem follows. □



Alternative solution. Given a unit vector u, denote by x_u the point on the inner curve with outer normal vector u. Draw a chord of outer curve which is tangent to the inner curve at x_u; denote by $r = r(u)$ and $l = l(u)$ the lengths of this chord at the right and left from x_u.

Arguing by contradiction, assume $r(u) \neq l(u)$ for any $u \in \mathbb{S}^1$. Since the functions r and l are continuous, we can assume that

$$(*) \qquad r(u) > l(u) \quad \text{for any} \quad u \in \mathbb{S}^1.$$

Prove that each of the following two integrals

$$\tfrac{1}{2}\cdot\int\limits_{\mathbb{S}^1} r^2(u)\cdot du \quad\text{and}\quad \tfrac{1}{2}\cdot\int\limits_{\mathbb{S}^1} l^2(u)\cdot du$$

gives the area between the curves. In particular, the integrals are equal to each other. The latter contradicts (∗). □

This is a problem of Serge Tabachnikov [see 24]. A closely related, so called *equal tangents problem* is discussed by the same author in [25].

Capture a sphere in a knot. We can assume that the knot lies on the sphere.

Fix a Möbius transformation $m\colon \mathbb{S}^2\to\mathbb{S}^2$ which is close to identity and not a rotation.

Note that m is a conformal map; that is, there is a function u defined on $\mathbb{S}^2$ such that

$$u(x)=\lim_{y,z\to x}\frac{|m(y)-m(z)|}{|y-z|}.$$

(The function u is called *conformal factor* of m.)

Since the area is preserved, we get

$$\frac{1}{\operatorname{area}\mathbb{S}^2}\cdot\int\limits_{\mathbb{S}^2} u^2=1.$$

By Bunyakovsky inequality,

$$\frac{1}{\operatorname{area}\mathbb{S}^2}\cdot\int\limits_{\mathbb{S}^2} u<1.$$

It follows that after a suitable rotation of $\mathbb{S}^2$, the map m decrease the length of the knot.

Iterate this construction and pass to the limit as $m\to\mathrm{id}$. This way you get a continuous one parameter family of Möbius transformations which shorten its length of the knot. Therefore it moves the knot in a hemisphere and allows the ball to escape. □

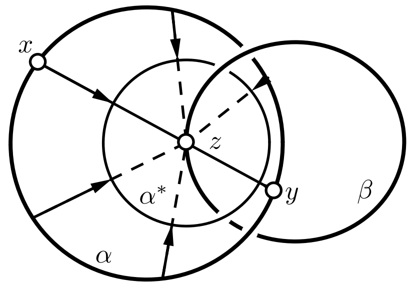
This is a problem of Zarathustra Brady, the given solution is based on the idea of David Eppstein [see 26].

Linked circles. Denote the linked circles by α and β.

Fix a point $x\in\alpha$. Note that one can find another point $y\in\alpha$ such that the interval $[xy]$ intersects β, say at the point z. Indeed, if this is not the case, rescaling α with center x shrinks α to x without crossing β. The latter contradicts that α and β are linked.

Consider the curve α^* which is the central projection of α from z onto the unit sphere around z. Clearly

$$\operatorname{length}\alpha \geqslant \operatorname{length}\alpha^*.$$



Note that α^* passes thru two antipodal points of the sphere, one corresponds to x and the other to y. Therefore

$$\operatorname{length}\alpha^* \geqslant 2{\cdot}\pi.$$

Hence the result follows. □

This problem was proposed by Frederick Gehring [see 7.22 in 27]; solutions and generalizations are surveyed in [28]. The presented the solution given by Michael Edelstein and Binyamin Schwarz in [29].

Surrounded area. Let C_1 and C_2 be the compact regions bounded by γ_1 and γ_2 correspondingly.

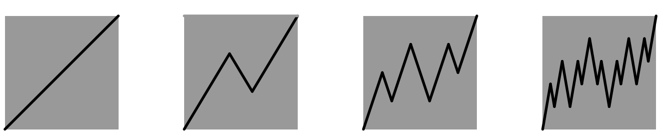
By Kirszbraun theorem, any 1-Lipschitz map $X \to \mathbb{R}^2$ defined on $X \subset \mathbb{R}^2$ can be extended to a 1-Lipschitz map on the whole $\mathbb{R}^2$. In particular, there is a 1-Lipschitz map $f\colon \mathbb{R}^2 \to \mathbb{R}^2$ such that $f(\gamma_2(v)) = f(\gamma_1(v))$ for any $v \in \mathbb{S}^1$.

Note that $f(C_2) \supset C_1$. Hence the statement follows. □

The Kirszbraun theorem appears in his thesis [see 30] and rediscovered later by Frederick Valentine in [31]. An interesting survey is given by Ludwig Danzer, Branko Grünbaum and Victor Klee in [32].

Crooked circle. A continuous function $f\colon [0,1] \to [0,1]$ will be called ε-crooked if $f(0) = 0$, $f(1) = 1$ and for any segment $[a,b] \subset [0,1]$ one can choose $a \leqslant x \leqslant y \leqslant b$ such that

$$|f(y) - f(a)| \leqslant \varepsilon \quad \text{and} \quad |f(x) - f(b)| \leqslant \varepsilon.$$



$\varepsilon = \frac{1}{2}$ $\qquad$ $\varepsilon = \frac{1}{3}$ $\qquad$ $\varepsilon = \frac{1}{4}$ $\qquad$ $\varepsilon = \frac{1}{5}$

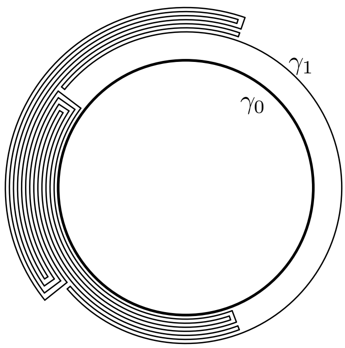
A sequence of $\frac{1}{n}$-crooked maps can be constructed recursively. Guess the construction from the diagram.

Now, start with the unit circle, $\gamma_0(t) = (\cos\frac{t}{2\cdot\pi}, \sin\frac{t}{2\cdot\pi})$. Fix a sequence of positive numbers ε_n which converges to zero very fast.

Construct recursively a sequence of simple closed curves $\gamma_n\colon [0,1] \to$ $\to \mathbb{R}^2$. Such that γ_{n+1} runs outside of the disc bounded by γ_n and

$$|\gamma_{n+1}(t) - \gamma_n \circ f_n(t)| < \varepsilon_n,$$

for some ε_n-crooked function f_n. (On the diagram you see an attempt to draw the first iteration.)



Denote by D the union of all discs bounded by γ_n. Clearly D is homeomorphic to an open disc. For the right choice of the sequence ε_n, the set D is bounded. By construction the boundary of D contains no simple curves. $\square$

In fact, the only curves in the boundary of the constructed set are constant, compare to the problem *Simple path* on page 99.

The proof use so called on *pseudo-arc* constructed by Bronisław Knaster in [33]. The construction is similar to the construction of the Cantor set. Here are few similar problems:

Construct three distinct open sets in $\mathbb{R}$ identical boundaries.

Construct three open discs in $\mathbb{R}^2$ which have the same boundary.

These discs are called *lakes of Wada*; it is described by Kunizô Yoneyama in [34].

Construct a Cantor set in $\mathbb{R}^3$ with non simply connected complement.

This example was is called *Antoine's necklace* [see 35].

Construct an open set in $\mathbb{R}^3$ with fundamental group isomorphic to the additive group of rational numbers.

More advanced examples include *Whitehead manifold*, *Dogbone space*, *Casson handle*; see also the problem "Conic neighborhood" on page 98.

Rectifiable curve. The 1-dimensional Hausdorff measure will be denoted as $\mathcal{H}_1$.

Set $L = \mathcal{H}_1(K)$. Without loss of generality, we may assume that K has diameter 1.

Since K is connected, we get

$$\mathcal{H}_1(B(x,\varepsilon)\cap K)\geqslant\varepsilon \tag{$*$}$$

for any $x\in K$ and $0<\varepsilon<\frac{1}{2}$.

Let $x_1,\dots,x_n$ be a maximal set of points in K such that

$$|x_i-x_j|\geqslant\varepsilon$$

for all $i\neq j$. From $(*)$ we have $n\leqslant 2\cdot L/\varepsilon$.

Note that there is a tree T_ε with the vertices $x_1,\dots,x_n$ and straight edges with length at most $2\cdot\varepsilon$ each. Therefore the total length of T_ε is below $2\cdot n\cdot\varepsilon\leqslant 4\cdot L$. By construction, T_ε is ε-close to K in the Hausdorff metric.

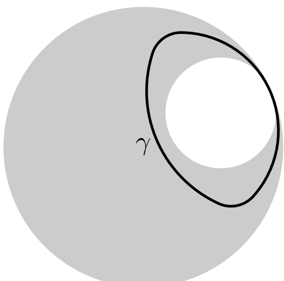
Clearly, there is a closed curve γ_ε which image is T_ε and its length is twice the total length of T_ε; that is,

$$\operatorname{length}\gamma_\varepsilon\leqslant 8\cdot L.$$

Passing to a partial limit of γ_ε as $\varepsilon\to 0$, we get the needed curve. □

In terms of measure, the optimal bound is $2\cdot L$; if in addition the diameter D is known then it is $2\cdot L-D$. The problem is due to Samuel Eilenberg and Orville Harrold [see 36]; it also appears in the book of Kenneth Falconer [see Exercise 3.5 in 37].

Typical convex curves. Denote by $\mathfrak{C}$ the space of closed convex curves in the plane equipped with Hausdorff metric. Recall that $\mathfrak{C}$ is locally compact. In particular, by Baire theorem, a countable intersection of everywhere dense open sets is everywhere dense.



Note that if a curve $\gamma\in\mathfrak{C}$ has nonzero second derivative at some point p, then it lies between two circles such that the one is tangent to the other from inside at p.

Fix these two circles. It is straightforward to check that there is $\varepsilon>0$ such that the Hausdorff distance from any convex curve γ squeezed between the circles to any convex n-gon is at least $\frac{\varepsilon}{n^{100}}$.

Fix a countable set of convex polygons $\mathfrak{p}_1,\mathfrak{p}_2,\dots$ which is dense in $\mathfrak{C}$. Denote by n_i the number of sides in $\mathfrak{p}_i$. For any positive integer k, consider the set $\Omega_k\subset\mathfrak{C}$ defined as

$$\Omega_k=\left\{\ \xi\in\mathfrak{C}\ \middle|\ |\xi-\mathfrak{p}_i|_H<\tfrac{1}{k\cdot n_i^{100}}\quad\text{for some}\quad i\ \right\},$$

where $|*-*|_H$ denotes the Hausdorff distance

From above we get that $\gamma\notin\Omega_k$ for some k.

Note that Ω_k is open and everywhere dense in $\mathfrak{C}$. Therefore

$$\Omega=\bigcap_k\Omega_k$$

is a G-delta dense set. Hence the statement follows. $\square$

It worth to note that the curvature of a convex curve is defined almost everywhere; it follows since monotonic functions are differentiable almost everywhere.

This problem states that typical convex curves have unexpected property. In fact, this is very common situation — typically we do not see the typical objects and these object often have surprising properties.

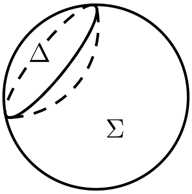
For example, as it was proved by Bernd Kirchheim, Emanuele Spadaro and László Székelyhidi in [38], a typical 1-Lipschitz maps from the plane to itself preserves the length of all curves. The same way one could show that boundary of typical open set in the plane contain no nontrivial curves in their boundary, altho the construction of a concrete example is not trivial; see "Crooked circle", page 7. More problems of that type are surveyed by Tudor Zamfirescu in [39].

Chapter 2

Surfaces

We assume that the reader is familiar with smooth surfaces and the related definitions including intrinsic metric, geodesics, convex and saddle surfaces as well as different types of curvature. An introductory course in differential geometry should cover all necessary background material; see for example [3, §28–29] or [4].

Convex hat



Let Σ be a smooth closed convex surface in $\mathbb{R}^3$ and Π be a plane which cuts from Σ a disc Δ. Assume that the reflection of Δ in Π lies inside of Σ. Show that Δ is convex *in the intrinsic metric of Σ; that is, if the ends of a minimizing geodesic in Σ lie in Δ, then whole geodesic lies in Δ.*

Semisolution. Let γ be a minimizing geodesic with the ends in Δ.

Assume $\gamma\backslash\Delta \neq \varnothing$. Denote by $\hat\gamma$ the curve formed by $\gamma\cap\Delta$ and the reflection on $\gamma\backslash\Delta$ in Π. Note that

$$\operatorname{length}\hat\gamma = \operatorname{length}\gamma$$

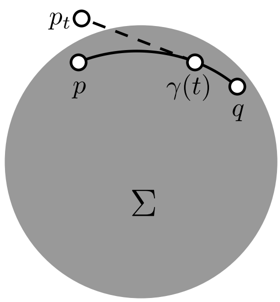
and $\hat\gamma$ runs partly along Σ and partly outside of Σ, but does not get inside of Σ.

Denote by $\bar\gamma$ the closest point projection of $\hat\gamma$ on Σ. Since Σ is convex, the closest point projection shrinks the length. Therefore the curve $\bar\gamma$ lies in Σ, it has the same ends as γ and

$$\operatorname{length}\bar\gamma < \operatorname{length}\gamma.$$

It means that γ is not length minimizing, a contradiction. □

Involute of geodesic



Let Σ be a smooth closed strictly convex surface in $\mathbb{R}^3$ and $\gamma\colon [0,\ell] \to \Sigma$ be a unit-speed minimizing geodesic in Σ. Set $p = \gamma(0)$, $q = \gamma(\ell)$ and

$$p_t = \gamma(t) - t\cdot\gamma'(t),$$

where $\gamma'(t)$ denotes the velocity vector of γ at t.

Show that for any $t \in (0,\ell)$, one cannot see *q from p_t; that is, the line segment $[p_t q]$ intersects Σ at a point distinct from q.*

Simple geodesic

Let Σ be a complete unbounded convex surface in $\mathbb{R}^3$. Show that there is a two-sided infinite geodesic in Σ with no self-intersections.

Let us review couple of statements about Gauss curvature which might help to solve the problem [see §28 in 3, for more details].

If Σ is a convex surface in $\mathbb{R}^3$ then its Gauss curvature is nonnegative.

Assume that a simply connected region Ω in a surface Σ is bounded by a closed broken geodesic γ. Denote by $\kappa(\Omega)$ the integral of Gauss curvaure along Ω.

For any point $p \in \Sigma$ consider outer unit normal vector $n(p) \in \mathbb{S}^2$. Then

$$\kappa(\Omega) = \operatorname{area}[n(\Omega)]$$

and by Gauss–Bonnet formula

$$\kappa(\Omega) = 2\cdot\pi - \sigma(\gamma),$$

where $\sigma(\gamma)$ denotes the sum of the signed exterior angles of γ. In particular, $|\sigma(\gamma)| \leqslant 2\cdot\pi$.

Geodesics for birds

The *total curvature* of γ is defined as the integral of its curvature. That is, if a curve $\gamma\colon [a,b] \to \mathbb{R}^3$ has unit speed parametrization, then the total curvature of γ equals to

$$\int_a^b |\gamma''(t)|\cdot dt,$$

the vector $\gamma''(t)$ is called *curvature vector* and its magnitude $|\gamma''(t)|$ is the *curvature* of γ at time t. The above definition has sense for $C^{1,1}$ smooth curves, that is, if $\gamma'(t)$ is locally Lipschitz; in this case the curvature $|\gamma''(t)|$ defined almost everywhere.

The *geodesics* in the following problem are defined as the curves locally minimizing the length; that is, a sufficiently short arc of the curve containing the given value of parameter is length minimizing.

🕮 *Let $f\colon \mathbb{R}^2 \to \mathbb{R}$ be a smooth ℓ-Lipschitz function. Let $W \subset \mathbb{R}^3$ be the epigraph of f; that is,*

$$W = \left\{\, (x, y, z) \in \mathbb{R}^3 \;\middle|\; z \geqslant f(x, y) \,\right\}.$$

Equip W with the induced intrinsic metric.

Show that any geodesic in W has total curvature at most $2{\cdot}\ell$.

Actually, geodesics in W are $C^{1,1}$-smooth; in particular, the formula for total curvature mentioned above makes sense. This is an easy exercise in real analysis which can be also taken as granted.

Immersed surface

🕮 *Let Σ be a connected immersed surface in $\mathbb{R}^3$ with strictly positive Gauss curvature and nonempty boundary $\partial\Sigma$. Assume $\partial\Sigma$ lies in a plane Π and whole Σ lies on one side from Π. Prove that Σ is an embedded disc.*

Periodic asymptote

🕮 *Let Σ be a closed smooth surface with non-positive curvature and γ be a geodesic in Σ. Assume that γ is not periodic and the curvature of Σ vanish at every point of γ. Show that γ does not have a periodic asymptote; that is, there is no periodic geodesic δ such that the distance from $\gamma(t)$ to δ converges to 0 as $t \to \infty$.*

Saddle surface

Recall that a smooth surface Σ in $\mathbb{R}^3$ is called *saddle* at point p if its principle curvatures at this point have opposite signs. We say that Σ is *saddle* if it saddle at all points.

🕮 *Let Σ be a saddle surface in $\mathbb{R}^3$ homeomorphic to a disc. Assume that orthogonal projection to (x, y)-plane maps the boundary of Σ injectively to convex closed curve. Show that the orthogonal projection to (x, y)-plane is injective on whole Σ.*

In particular, Σ is a graph $z = f(x, y)$ for a function f defined on a convex figure in the (x, y)-plane.

Asymptotic line

The saddle surfaces are defined in the previous problem.

Recall that *asymptotic line* on the smooth surface $\Sigma \subset \mathbb{R}^3$ is a curve always tangent to an *asymptotic direction* of Σ; that is, a direction with vanishing normal curvature.

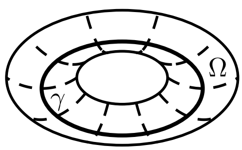
📖 *Let $\Sigma \subset \mathbb{R}^3$ be the graph $z = f(x, y)$ of smooth function f and γ be a closed smooth asymptotic line in Σ. Assume Σ is saddle in a neighborhood of γ. Show that the projection of γ to the (x, y)-plane cannot be star-shaped.*

Minimal surface

Recall that a smooth surface in $\mathbb{R}^3$ is called *minimal* if its mean curvature vanish at all points. The *mean curvature* is defined as the sum of the principle curvatures at the point.

📖 *Let Σ be a minimal surface in $\mathbb{R}^3$ which has boundary on a unit sphere. Assume Σ passes thru the center of the sphere. Show that the area of Σ is at least π.*

Round gutter*



A round gutter is the surface shown on the picture.

Formally: consider torus T; that is, a surface generated by revolving a circle in $\mathbb{R}^3$ about an axis coplanar with the circle. Let $\gamma \subset T$ be one of the circles in T which locally separates positive and negative curvature on T; a plane containing γ is tangent to T at all points of γ. Then a neighborhood of γ in T is called *round gutter* and the circle γ is called its *main latitude.*

📖 *Let $\Omega \subset \mathbb{R}^3$ is a round gutter with main latitude γ. Assume $\iota\colon \Omega \to \mathbb{R}^3$ is a smooth length-preserving embedding which is sufficiently close to the identity. Show that γ and $\iota(\gamma)$ are congruent; that is, there is a motion of $\mathbb{R}^3$ which sends γ to $\iota(\gamma)$*

Non-contractible geodesics

📖 *Give an example of a non-flat metric on the 2-torus such that it has no contractible geodesics.*

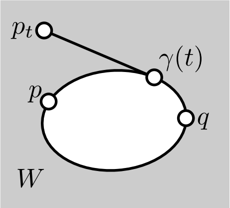
Two discs

🕮 *Let Σ_1 and Σ_2 be two smoothly embedded open discs in $\mathbb{R}^3$ which have a common closed smooth curve γ. Show that there is a pair of points $p_1 \in \Sigma_1$ and $p_2 \in \Sigma_2$ with parallel tangent planes.*

Semisolutions

Involute of geodesic. Let W be the closed unbounded set formed by Σ and its exterior points. Fix $t \in (0, \ell)$; denote by γ_t the concatenation of the line segment $[p_t\gamma(t)]$ and the arc $\gamma|_{[t,\ell]}$. The key step is to show the following:

$(*)$ *The curve γ_t is a minimizing geodesic in the intrinsic metric induced on W.*



Try to prove it before reading further.

Let Π_t be the tangent plane to Σ at $\gamma(t)$. Consider the curve $\alpha(t) = p_t$. Note that $\alpha(t) \in \in \Pi_t$, $\alpha'(t) \perp \Pi_t$ and $\alpha'(t)$ points to the side of Π_t opposite from Σ.

It follows that for any $x \in \Sigma$ the function

$$t \mapsto |x - p_t| \quad \text{and, therefore,} \quad t \mapsto |x - p_t|_W$$

are non-decreasing; here $|x - p_t|_W$ stays for the intrinsic distance from x to p_t in W.

On the other hand, by construction

$$|q - p_t|_W \leqslant |q - p|_\Sigma;$$

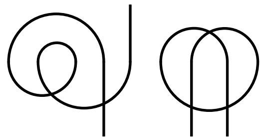
therefore, from above

$$|q - p_t|_W = |q - p|_\Sigma$$

for any t. Hence $(*)$ follows.

Now assume q is visible from p_t for some t; that is, the line segment $[qp_t]$ intersects Σ only at q. From above, γ_t coincides with the line segment $[qp_t]$. On the other hand γ_t contains $\gamma(t) \in \Sigma$, a contradiction. $\square$

This problem is based on an observation used by Anatoliy Milka in the proof of his (beautiful) generalization of comparison theorem for convex surfaces [see 40].



Simple geodesic. Look at two combinatoric types of self intersections shown on the diagram. One of the types can and the other can not appear as self intersections of geodesic on an unbounded convex surface. Try to determine which is which before reading further.

Let γ be a two-sided infinite geodesic in Σ. The following is the key statement in the proof.

$(*)$ *The geodesic γ contains at most one simple loop.*

To prove $(*)$, we use the following observation.

$(**)$ *The integral curvature ω of Σ cannot exceed $2{\cdot}\pi$.*

Indeed, since Σ is unbounded and convex, it surrounds a half-line. Consider a coordinate system with this half-line as the positive half of z-axis. In these coordinates, the surface Σ is described as a graph $z = f(x, y)$ for a convex function f. In particular the outer normal vectors to Σ point in the south hemisphere. Therefore the area of spherical image of Σ is at most $2{\cdot}\pi$. The area of this image is the integral of Gauss curvature along Σ. Hence $(**)$ follows.

From Gauss–Bonnet formula, we get the following. If φ is the angle at the base of a simple geodesic loop then the integral curvature surrounded by the loop equals to $\pi + \varphi$. In particular there are no concave loops.

Now assume $(*)$ does not hold, so a geodesic has two simple loops. Note that the discs bounded by loops have to overlap, otherwise the curvature of Σ will axceed $2{\cdot}\pi$. But if they overlap then it is easy to show that the curve also contains a concave loop, which contradicts the observation above.[1]

If a geodesic γ has a self-intersection, then it contains a simple loop. From $(*)$, there is only one such loop; it cuts a disc from Σ and can go around it either clockwise or counterclockwise. This way we divide all the self-intersecting geodesics into two sets which we will call *clockwise* and *counterclockwise*.

Note that the geodesic $t \mapsto \gamma(t)$ is clockwise if and only if $t \mapsto \gamma(-t)$ is counterclockwise. The sets of clockwise and counterclockwise are open and the space of geodesics is connected. It follows that there are geodesics which are, neither clockwise, nor counterclockwise. These geodesics have no self-intersections. $\square$

[1] This observation implies that the right picture on the diagram above can not be realized by a geodesic.

The problem is due to Stephan Cohn-Vossen, [41, Satz 9]; generalizations were obtained by Vladimir Streltsov and Alexandr Alexandrov [in 42] and by Victor Bangert [in 43].

Geodesics for birds. Fix a unit-speed geodesic in W, say

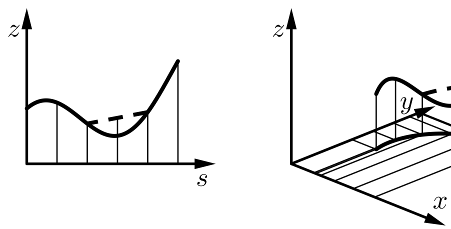
$$\gamma\colon t\mapsto (x(t),y(t),z(t)).$$

We can assume that γ is defined on a closed interval $[a,b]$. The key step is to show the following:

$(*)$ *The function $t\mapsto z$ is concave.*

Parametrize the plane curve $t\mapsto (x(t),y(t))$ by arclength s and reparametrize γ by s.

Note that the function $s\mapsto z$ is concave. If not, one could shorten γ by moving its points up, in the direction of z-axis, and keeping its ends fixed. Moreover, this deformation can be performed in an arbitrary small neighborhood of some point on γ. After the deformation, the curve still lies in W. The latter contradicts that γ locally length minimizing.



Finally note that concavity of $s\mapsto z$ is equivalent to the concavity of $t\mapsto z$. Hence $(*)$ follows.

Since f is smooth, the curve $\gamma(t)$ is $C^{1,1}$; that is, its first derivative $\gamma'(t)$ is a well defined Lipschitz function. It follows that second derivative $\gamma''(t)$ is defined almost everywhere.

Since $z(t)$ is concave, we have $z''(t)\leqslant 0$. Since f is ℓ-Lipschitz, $z(t)$ is $\frac{\ell}{\sqrt{1+\ell^2}}$-Lipschitz. It follows that

$$\int_a^b|z''(t)|\leqslant 2\cdot\tfrac{\ell}{\sqrt{1+\ell^2}}.$$

The curvature vector $\gamma''(t)$ is perpendicular to the surface. Since the surface has slope at most ℓ, we get

$$|\gamma''(t)|\leqslant|z''(t)|\cdot\sqrt{1+\ell^2}.$$

Hence

$$\int_a^b |\gamma''(t)| \leqslant 2\cdot\ell. \qquad \square$$

The statement holds for general ℓ-Lischitz function, not necessary smooth. The given bound is optimal, the equality is reached for both side infinite geodesic on the graph of

$$f(x,y) = -\ell\cdot\sqrt{x^2+y^2}.$$

The problem is due to David Berg [see 44] the same bound for convex ℓ-Lipschitz surfaces was proved earlier by Vladimir Usov [see 45]. The observation $(*)$ is called *Liberman's lemma*; it was used yet earlier to bound the total curvature of a geodesic on a convex surface [see 46].[2] This lemma is often useful when geodesics on convex surfaces are considered.

Immersed surface. Let ℓ be a linear function which vanishes on Π and is positive on Σ.

Let z_0 be a point of maximum of ℓ on Σ; set $s_0 = \ell(z_0)$. Given $s < s_0$, denote by Σ_s the connected component of z_0 in $\Sigma\cap\ell^{-1}([s,s_0])$. Note that for all s sufficiently close to s_0 we have

◇ Σ_s is an embedded disc;

◇ $\partial\Sigma_s$ is convex plane curve.

Applying open-closed argument, we get that the same holds for all $s\in[0,s_0)$.

Since Σ is connected, $\Sigma_0 = \Sigma$. Hence the result follows. $\square$

This problem is discussed in the lectures of Mikhael Gromov [see $\S\frac12$ in 47].

Periodic asymptote. Assume the contrary; that is, there is a geodesic γ on the surface Σ with a periodic asymptote δ.

Passing to a finite cover of Σ, we can ensure that the asymptote has no self intersections. In this case the restriction $\gamma|_{[a,\infty)}$ has no self-intersections, if a is large enuf.

Cut Σ along $\gamma([a,\infty))$ and then cut from the obtained surface an infinite triangle $\triangle$. The triangle $\triangle$ has two sides formed by both sides of cuts along γ; let us denote these sides of $\triangle$ by γ_- and γ_+. Note that

$$(*) \qquad \operatorname{area}\triangle < \operatorname{area}\Sigma < \infty$$

[2] It was a part of the thesis of Joseph Liberman, defended couple of months before his death in the WWII.

and both sides $\gamma_\pm$ form infinite minimizing geodesics in $\triangle$.

Consider the Busemann function f for γ_+; denote by $\ell(t)$ the length of the level curve $f^{-1}(t)$. Let $-\kappa(t)$ be the total curvature of the sup-level set $f^{-1}([t,\infty))$. From Gauss–Bonnet formula,

$$\ell'(t) = \kappa(t). \tag{$**$}$$

The level curve $f^{-1}(t)$ can be parametrized by a unit-speed curve, say $\theta_t\colon [0,\ell(t)] \to \triangle$. By coarea formula we have

$$\kappa'(t) = -\int\limits_0^{\ell(t)} K_{\theta_t(\tau)}\cdot d\tau,$$

where K_x denotes the Gauss curvature of Σ at the point x. Since $K_{\theta_t(0)} = K_{\theta_t(\ell_t)} = 0$ and the surface is smooth, there is a constant C such that $|K_{\theta_t(\tau)}| \leqslant C{\cdot}\ell(t)^2$ for all t, τ. Therefore

$$\kappa'(t) \leqslant C{\cdot}\ell(t)^3 \tag{${}^{\,*}_{**}$}$$

Together, $(**)$ and $({}^{\,*}_{**})$ imply that there is $\varepsilon > 0$ such that

$$\ell(t) \geqslant \frac{\varepsilon}{t-a}$$

for any large t. By the coarea formula we get

$$\operatorname{area}\triangle = \int\limits_a^\infty \ell(t) = \infty;$$

the latter contradicts $(*)$. $\square$

I've learned the problem from Dmitri Burago and Sergei Ivanov, it is originated from a discussion with Keith Burns, Michael Brin and Yakov Pesin.

Here is a motivation: assume Σ be a closed surface with non-positive curvature which is not flat. The space Γ of all unit-speed geodesics $\gamma\colon \mathbb{R} \to \Sigma$ can be identified with the unit tangent bundle $\mathrm{U}\Sigma$. In particular Γ comes with a natural choice of measure. Denote by $\Gamma_0 \subset \Gamma$ the set of geodesics which run in the set of zero curvature all the time. It is expected that Γ_0 has vanishing measure. In all known examples Γ_0 contains only periodic geodesics in only finitely many homotopy classes [see also 48].

Saddle surface. Denote by Σ° the interior of Σ. Fix a plane Π. Note that the intersection $\Pi \cap \Sigma^\circ$ locally looks like a curve or two curves intersecting transversally; in the latter case Π is tangent to Σ° at the cross-point.

Further note that $\Pi \cap \Sigma^\circ$ has no cycle. Otherwise Σ fails to be saddle at the point of the disc surrounded by the cycle which maximize the distance to Π.

Note that if Σ is not a graph then there is a point $p \in \Sigma$ with vertical tangent plane; denote this plane by Π. The intersection $\Pi \cap \Sigma$ has cross-point at p.

Since the boundary of Σ projects injectively to a closed convex curve in (x, y)-plane, the intersection of $\Pi \cap \partial\Sigma$ has at most 2 points — these are the only endpoints of $\Pi \cap \Sigma$.

It follows that the connected component of p in $\Pi \cap \Sigma$ is a tree with a vertex of degree 4 at p and at most two end-points, a contradiction. □

The proof above is based on the observation that for any saddle surface Σ and plane Π, each connected component of $\Sigma \backslash \Pi$ is unbounded or contains points on the boundary of Σ. One can define *generalized saddle surfaces* as arbitrary (non necessarily smooth) surface which satisfies this condition. The geometry of these surfaces is far from being understood, Samuil Shefel has number of beautiful results about them, see [49] and references there in.

Our problem also holds for generalized saddle surfaces, but the proof I know is quite involved (I also know an easy fake proof).

The idea in the proof can be used to produce a short proof without any calculation of the result Richard Schoen and Shing-Tung Yau, stating that a harmonic map of degree 1 from a compact surface to a compact negatively curved surface is a diffeomorphism [see 50].

Asymptotic line. Arguing by contradiction, assume that the projection $\bar\gamma$ of γ on (x, y)-plane is star shaped with respect to the origin.

Consider the function

$$h(t) = (d_{\bar\gamma(t)} f)(\gamma(t)).$$

Direct calculations show $h'(t) \neq 0$. In particular $h(t)$ is a strictly monotonic function of $\mathbb{S}^1$, a contradiction. □

The problem is discussed by Dmitri Panov in [51].

Minimal surface. Without loss of generality we may assume that the sphere is centered at the origin of $\mathbb{R}^3$.

Let h be the restriction of the function $x \mapsto \frac{1}{2} \cdot |x|^2$ to the surface Σ. Direct calculations show that $\Delta_\Sigma h \leqslant 2$. Applying the divergence theorem for $\nabla_\Sigma h$ in $\Sigma_r = \Sigma \cap B(0, r)$, we get

$$2 \cdot \operatorname{area} \Sigma_r \leqslant r \cdot \operatorname{length}[\partial \Sigma_r].$$

Set $a(r) = \operatorname{area}\Sigma_r$. By coarea formula, $a'(r) \geqslant \operatorname{length}[\partial\Sigma_r]$ at almost all r. Therefore the function

$$f\colon r \mapsto \frac{\operatorname{area}\Sigma_r}{r^2}$$

is non-decreasing in the interval $(0,1)$.

Since $f(r)\to\pi$ as $r\to 0$, the result follows. □

We described a partial case of so called *monotonicity formula* for minimal surfaces.

The same argument shows that if 0 is a double point of Σ then $\operatorname{area}\Sigma \geqslant 2\cdot\pi$. This observation was used in the proof that the minimal disc bounded by a simple closed curve with total curvature $\leqslant 4\cdot\pi$ is necessarily embedded. It was proved by Tobias Ekholm, Brian White and Daniel Wienholtz [see 23]; an amusing simplification and generalization was obtained by Stephan Stadler. This result also implies that any embedded circle of total curvature at most $4\cdot\pi$ is unknot. The latter was proved inependently by István Fáry [in 20] and John Milnor [in 21].

Note that if we assume in addition that the surface is a disc, then the statement holds for any saddle surface. Indeed, denote by S_r the sphere of radius r concentrated with the unit sphere. Then according to the problem "A curve in a sphere" [page 6],

$$\operatorname{length}[\partial\Sigma_r] \geqslant 2\cdot\pi\cdot r.$$

Then by coarea formula we get $\operatorname{area}\Sigma \geqslant \pi$.

On the other hand there are saddle surfaces homeomorphic to the cylinder that may have arbitrary small area in the ball.

If Σ does not pass thru the center and we only know the distance, say r, from the center to Σ, then the optimal bound is $\pi\cdot(1-r^2)$. It was conjectured for about 40 years and proved by Simon Brendle and Pei-Ken Hung in [52]; their proof is based on a similar idea and quite elementary. Earlier Herbert Alexander, David Hoffman and Robert Osserman proved it in two cases (1) for discs and (2) for arbitrary area minimizing surfaces, any dimension and codimension [see 53, 54].

Round gutter. Without loss of generality, we can assume that the length of γ is $2\cdot\pi$ and its intrinsic curvature is 1 at all points.

Let K be the convex hull of $\Omega' = \iota(\Omega)$. Part of Ω' touch the boundary of K and part lies in the interior of K. Denote by γ' the curve in Ω' dividing these two parts.

First note that the Gauss curvature of Ω' has to vanish at the points of γ'; in other words, $\gamma' = \iota(\gamma)$. Indeed, since γ' lies on convex part, the Gauss curvature at the points of γ' has to be non-negative.

On the other hand γ' bounds a flat disc in ∂K; therefore its integral intrinsic curvature has to be $2{\cdot}\pi$. If the Gauss curvature is positive at some point of γ', then total intrinsic curvature of γ' has to be $< 2{\cdot}\pi$, a contradiction.

On the other hand γ' is an asymptotic line. Indeed, if the direction of γ' is not asymptotic at some t_0 then $\gamma'(t \pm \varepsilon)$ lies the interior of K for some small $\varepsilon > 0$, a contradiction.

Therefore, as the space curve, γ' has to be a curve with constant curvature 1 and it should be closed. Any such curve is congruent to a unit circle. □

It is not known if Ω' is congruent to Ω.

The solution presented above is based on my answer to the question of Joseph O'Rourke [see 55]. Here are some related statements.

- ⋄ A gutter is second order rigid; this was proved by Eduard Rembs in [56], see also [57, p. 135].
- ⋄ Any second order rigid surface does not admit analytic deformation [proved by Nikolay Efimov, see 57, p. 121] and for the surfaces of revolution, the assumption of analyticity can be removed [proved by Idzhad Sabitov, see 58].

Non-contractible geodesics. Take a torus of revolution T. It has a family *meridians* — a family of circles which form closed geodesics.

Note that a geodesic on T is either a meridian or it intersects meridians transversally. In the latter case all the meridiangs are crossed by the geodesic in the same direction.

A contactable curve has to cross each meridian equal number of times in both directions. Hence no geodesics of the torus are contractible. □

I learned this problem from the book of Mikhael Gromov [see 59], where it is attributed to Y. Colin de Verdière. I do not know any generic metric of that type.

Two discs. Choose a continuous map $h\colon \Sigma_1 \to \Sigma_2$ which is identical on γ. Let us prove that for some $p_1 \in \Sigma_1$ and $p_2 = h(p_1) \in \Sigma_2$ the tangent plane $\mathrm{T}_{p_1}\Sigma_1$ is parallel to the tangent plane $\mathrm{T}_{p_2}\Sigma_2$; this is stronger than required.

Arguing by contradiction, assume that such point does not exist. Then for each $p \in \Sigma_1$ there is unique line $\ell_p \ni p$ which is parallel to each of the tangent planes $\mathrm{T}_p\Sigma_1$ and $\mathrm{T}_{h(p)}\Sigma_2$.

Note that the lines ℓ_p form a tangent line distribution over Σ_1 and ℓ_p is tangent to γ at any $p \in \gamma$.

Let Δ be the disc in Σ_1 bounded by γ. Consider the doubling of Δ along γ; it is diffeomorphic to $\mathbb{S}^2$. The line distribution ℓ lifts to a line distribution on the doubling. The latter contradicts the hairy ball theorem. □

This proof was suggested nearly simultaneously by Steven Sivek and Damiano Testa [see 60].

Note that the same proof works in case Σ_i are oriented open surfaces such that γ cuts a compact domain in each Σ_i.

There are examples of three disks Σ_1, Σ_2 and Σ_3 with a common closed curve γ such that there no triple of points $p_i \in \Sigma_i$ with parallel tangent planes. Such examples can be found among ruled surfaces [see 61].

Chapter 3

Comparison geometry

In this chapter we consider Riemannian manifolds with curvature bounds.

This chapter is very demanding; we assume that the reader is familiar with shape operator and second fundamental form, equations of Riccati and Jacobi, comparison theorems and Morse theory. The classical book [62] covers all the necessary material.

Geodesic immersion*

An isometric immesion $\iota\colon N \looparrowright M$ from one Riemannian manifold to an other is called *totally geodesic* if it maps any geodesic in N to a geodesic in M.

Let M be a simply connected positively curved Riemannian manifold and $\iota\colon N \looparrowright M$ be a totally geodesic immersion. Assume that

$$\dim N > \tfrac{1}{2}\cdot\dim M.$$

Prove that ι is an embedding.

Semisolution. Set $n = \dim N$, $m = \dim M$.

Fix a smooth increasing strictly concave function φ. Consider the function $f = \varphi\circ\operatorname{dist}_N$.

Note that if f is smooth at some point $x \in M$ then the Hessian of f at x (briefly $\operatorname{hess}_x f$) has at least $n+1$ negative eigenvalues.

Moreover, at any point $x \notin \iota(N)$ the same holds in the barrier sense. That is, there is a smooth function h defined on M such that $h(x) = f(x)$, $h(y) \geqslant f(y)$ for any y and $\operatorname{hess}_x h$ has at least $n+1$ negative eigenvalues.

Use that $m < 2{\cdot}n$ and the described property to prove the following analog of Morse lemma for f.

($*$) *Given $x \notin \iota(N)$ there is a neighborhood $U \ni x$ such that the set*

$$U_- = \{\, z \in U \mid f(z) < f(x) \,\}$$

is simply connected.

Since M is simply connected, any closed curve in $\iota(N)$ can be contracted by a disc, say $s_0 \colon \mathbb{D} \to M$.

Applying the claim ($*$), one can construct an f-decreasing homotopy which starts at s_0 and ends in $\iota(N)$. That is, a homotopy $s_t \colon \mathbb{D} \to M$, $t \in [0,1]$ such that $s_t(\partial\mathbb{D}) \subset \iota(N)$ for any t and $s_1(\mathbb{D}) \subset \iota(N)$. It follows that $\iota(N)$ is simply connected.

Finally note that if $\iota \colon N \to M$ has a self-intersection, then the image $\iota(N)$ is not simply connected. Hence the result follows. $\square$

The statement was proved by Fuquan Fang, Sérgio Mendonça and Xiaochun Rong in [63]. The main idea was discovered by Burkhard Wilking [see 64].

Geodesic hypersurface

The totally geodesic embedding is defined before the previous problem.

📖 *Assume a compact connected positively curved manifold M has a totally geodesic embedded hypersurface. Show that M or its double cover is homeomorphic to the sphere.*

If convex, then embedded

📖 *Let M be a complete simply connected Riemannian manifold with non-positive curvature and dimension at least* 3. *Prove that any immersed locally convex compact hypersurface Σ in M is embedded.*

Let us summarize some statements about complete simply connected Riemannian manifolds with non-positive curvature.

By Cartan–Hadamard theorem, for any point $p \in M$ the exponential map $\exp_p \colon \mathrm{T}_p \to M$ is a diffeomorphism. In particular M is diffeomorphic to the Euclidean space of the same dimension. In particular, any geodesic in M is minimizing, and any two points in M are connected by unique minimizing geodesic,

Further, M is a CAT[0] space; that is, it satisfies a global angle comparison which we are about to describe. Assume $[xyz]$ is a triangle in M; that is, three distinct points connected pairwise by geodesics.

Consider its model triangle $[\tilde x\tilde y\tilde z]$ in the Euclidean plane; that is, a triangle with the coresponding side lengths as in $[xyz]$. Then each angle in $[xyz]$ can not axceed the corresponding angle in $[\tilde x\tilde y\tilde z]$. This inequality can be written as

$$\tilde\measuredangle(y\,{}^{x}_{z}) \geqslant \measuredangle[y\,{}^{x}_{z}],$$

where $\measuredangle[y\,{}^{x}_{z}]$ denotes the angle of the hinge $[y\,{}^{x}_{z}]$ formed by two geodesics $[yx]$ and $[yz]$ and $\tilde\measuredangle(y\,{}^{x}_{z})$ denotes the corresponding angle in the model triangle $[\tilde x\tilde y\tilde z]$.

From this comparison it follows that any connected closed locally convex sets in M is globally convex. In particular, if Σ is embedded then it bounds a convex set.

Immersed ball*

Prove that any immersed locally convex hypersurface $\iota\colon \Sigma \looparrowright M$ in a compact positively curved manifold M of dimension $m \geqslant 3$, is the boundary of an immersed ball. That is, there is an immersion of a closed ball $f\colon \bar B^m \looparrowright M$ and a diffeomorphism $h\colon \Sigma \to \partial\bar B^m$ such that $\iota = f\circ h$.

Minimal surface in the sphere

A smooth n-dimensional surface Σ in an m-dimensional Riemannian manifold M is called minimal if it locally minimized the n-dimensional area; that is, sufficiently small regions of Σ do not admit area decreasing deformations with fixed boundary.

The minimal surfaces can be also defined via mean curvature vector as follows. Let $\mathrm{T} = \mathrm{T}\,\Sigma$ and $\mathrm{N} = \mathrm{N}\,\Sigma$ correspondingly tangent and normal bundle. Let s denotes the second fundamental form of Σ; it is a quadratic from on T with values in N, see the remark after problem “Hypercurve” below. Given an orthonormal basis (e_i) in T_x, set

$$H_x = \sum_i s(e_i, e_i).$$

The vector H_x lies in the normal space N_x and it does not depend on the choice of orthonormal basis (e_i). This vector H_x is called the mean curvature vector at $x \in \Sigma$.

We say that Σ is *minimal* if $H \equiv 0$.

Let Σ be a closed n-dimensional minimal surface in the unit m-dimensional sphere $\mathbb{S}^m$. Prove that $\operatorname{vol}_n \Sigma \geqslant \operatorname{vol}_n \mathbb{S}^n$.

Hypercurve

The Riemannian curvature tensor R can be viewed as an operator $\mathbf{R}$ on the space of tangent bi-vectors $\bigwedge^2 \mathrm{T}$; it is uniquely defined by identity

$$\langle \mathbf{R}(X \wedge Y), V \wedge W \rangle = \langle R(X,Y)V, W \rangle.$$

The operator $\mathbf{R}\colon \bigwedge^2 \mathrm{T} \to \bigwedge^2 \mathrm{T}$ is called *curvature operator* and it is said to be *positive definite* if $\langle \mathbf{R}(\varphi), \varphi \rangle > 0$ for all non zero bi-vector $\varphi \in \bigwedge^2 \mathrm{T}$.

Let $M^m \hookrightarrow \mathbb{R}^{m+2}$ be a closed smooth m-dimensional submanifold and let g be the induced Riemannian metric on M^m. Assume that sectional curvature of g is positive. Prove that the curvature operator of g is positive definite.

The second fundamental form for manifolds of arbitrary codimension which we are about to describe might help to solve this problem.

Assume M is a smooth submanifold in $\mathbb{R}^m$. Given a point $p \in M$ denote by T_p and $\mathrm{N}_p = \mathrm{T}_p^\perp$ the tangent and normal spaces of M at p. The *second fundamental form* of M at p is defined as

$$s(X,Y) = (\nabla_X Y)^\perp,$$

where $(\nabla_X Y)^\perp$ denotes the orthogonal projection of covariant derivative $\nabla_X Y$ onto the normal bundle.

The curvature tensor of M can be found from the second fundamental form using the following formula

$$\langle R(X,Y)V, W \rangle = \langle s(X,W), s(Y,V) \rangle - \langle s(X,V), s(Y,W) \rangle,$$

which is direct generalization of the formula for Gauss curvature of surface.

Horo-sphere

We say that a Riemannian manifold has negatively pinched sectional curvature, if its sectional curvatures at all point in all sectional direction lie in an interval $[-a^2, -b^2]$, for fixed constants $a > b > 0$.

Let M be a complete Riemannian manifold and γ is a ray in M; that is, $\gamma\colon [0,\infty) \to M$ is a minimizing unit-speed geodesic.

The *Busemann function* $\mathrm{bus}_\gamma\colon M \to \mathbb{R}$ is defined by

$$\mathrm{bus}_\gamma(p) = \lim_{t\to\infty} \left(|p - \gamma(t)|_M - t \right).$$

From the triangle inequality, the expression under the limit is non-increasing in t; therefore the limit above is defined for any p.

A *horo-sphere* in M is defined as a level set of a Busemann function in M.

We say that a complete Riemannian manifold M has *polynomial volume growth* if for some (and therefore any) $p \in M$, we have

$$\operatorname{vol} B(p,r)_M \leqslant C\cdot(r^k+1),$$

where $B(p,r)_M$ denotes the ball in M and C, k are real constants.

Let M be a complete simply connected manifold with negatively pinched sectional curvature and $\Sigma \subset M$ be an horo-sphere in M. Show that Σ with the induced intrinsic metric has polynomial volume growth.

Minimal spheres

Recall that two subsets A and B in a metric space X are called *equidistant* if the distance function $\operatorname{dist}_A\colon X \to \mathbb{R}$ is constant on B and dist_B is constant on A.

The minimal surfaces are defined on page 32.

Show that a 4-dimensional compact positively curved Riemannian manifold cannot contain infinite number of mutually equidistant minimal 2-spheres.

Positive curvature and symmetry^{+}

Assume $\mathbb{S}^1$ acts isometrically on a 4-dimensional positively curved closed Riemannian manifold. Show that the action has at most 3 isolated fixed points.

The following statement might be useful. If (M,g) is a Riemannian manifold with sectional curvature $\geqslant \kappa$ which admits a continuous isometric action of a compact group G, then the quotient space $A=(M,g)/G$ is an Alexandrov space with curvature $\geqslant \kappa$; that is, the conclusion of Toponogov comparison theorem holds in A.

For more on Alexandrov geometry read our book [65].

Energy minimizer

Let F be a smooth map from a closed Riemannian manifold M to a Riemannian manifold N. Then energy functional of F is defined as

$$E(F)=\int\limits_M |d_xF|^2\cdot d_x \operatorname{vol}_M.$$

We assume that
$$|d_xF|^2 = \sum_{i,j} a_{i,j}^2,$$
where $(a_{i,j})$ denote the components of the differential d_xF written in the orthonormal bases of the tangent spaces T_xM and $\mathrm{T}_{F(x)}N$.

Show that the identity map on $\mathbb{R}\mathrm{P}^m$ is energy minimizing in its homotopy class. Here we assume that $\mathbb{R}\mathrm{P}^m$ is equipped with canonical metric.

Curvature vs. injectivity radius$^+$

Let (M, g) be a closed Riemannian m-dimensional manifold. Assume average of sectional curvatures of (M, g) is 1. Show that the injectivity radius of (M, g) is at most π.

Solutions of this and the previous problems use that geodesic flow on the tangent bundle to a Riemannian manifold preserves the volume form; this is a corollary of Liouville's theorem on phase volume.

Almost flat manifold$^\circ$

Nil-manifolds form the minimal class of manifolds which includes a point, and has the following property: the total space of any principle $\mathbb{S}^1$-bundle over a nil-manifold is a nil-manifold.

The nil-manifolds can be also defined as the quotients of a connected nilpotent Lie group by a lattice.

A compact Riemannian manifold M is called ε-flat if its sectional curvature at all points in all directions lie in the interval $[-\varepsilon, \varepsilon]$.

The main theorem of Gromov in [66], states that for any positive integer n there is $\varepsilon > 0$ such that any ε-flat compact n-dimensional manifold with diameter at most 1 admits a finite cover by a nil-manifold. A more detailed proof can be found in [67] and a more precise statement can be found in [68].

Given $\varepsilon > 0$ construct a compact Riemannian manifold M of sufficiently large dimension which admits a Riemannian metric with diameter $\leqslant 1$ and sectional curvature $|K| < \varepsilon$, but does not admit a finite covering by a nil-manifold.

Approximation of a quotient

Let (M, g) be a compact Riemannian manifold and G be a compact Lie group acting by isometries on (M, g). Construct a sequence of *metrics g_n on a fixed manifold N such that (N, g_n) converges to the quotient space $(M, g)/G$ in the sense of Gromov–Hausdorff.*

Polar points$^\sharp$

Let M be a compact Riemannian manifold with sectional curvature at least 1 and the dimension at least 2. Prove that for any point $p \in M$ there is a point $p^* \in M$ such that

$$|p - x|_M + |x - p^*|_M \leqslant \pi$$

for any $x \in M$.

Isometric section*

Let M and W be compact Riemannian manifolds, $\dim W > \dim M$ *and $s\colon W \to M$ be a Riemannian submersion. Assume that W has positive sectional curvature. Show that s does not admit an isometric section; that is, there is no isometric embedding $\iota\colon M \hookrightarrow W$ such that $s \circ \iota(p) = p$ for any $p \in M$.*

Warped product

Let (M, g) and (N, h) be Riemannian manifolds and f be a smooth positive function defined on M. Consider the product manifold $W = M \times N$. Given a tangent vector $X \in \mathrm{T}_{(p,q)}W = \mathrm{T}_pM \times \mathrm{T}_pN$ denote by $X_M \in \mathrm{T}M$ and $X_N \in \mathrm{T}N$ its projections. Let us equip W with the Riemannian metric defined as

$$s(X, Y) = g(X_M, Y_M) + f^2{\cdot}h(X_N, Y_N).$$

The obtained Riemannian manifold (W, s) is called *warped product* of M and N with respect to $f\colon M \to \mathbb{R}$; it can be written as

$$(W, g) = (N, h) \times_f (M, g).$$

Assume M is an oriented 3-dimensional Riemannian manifold with positive scalar curvature and $\Sigma \subset M$ is an oriented smooth hypersurface which is area minimizing in its homology class.

Show that there is a positive smooth function $f\colon \Sigma \to \mathbb{R}$ such that the warped product $\mathbb{S}^1 \times_f \Sigma$ has positive scalar curvature; here Σ is equipped with the Riemannian metric induced from M.

No approximation$^\sharp$

Prove that if $p \neq 2$, then $\mathbb{R}^m$ equipped with the metric induced by the ℓ^p-norm cannot be a Gromov–Hausdorff limit of m-dimensional Riemannian manifolds (M_n, g_n) with $\mathrm{Ric}_{g_n} \geqslant C$ for some fixed real constant C.

Area of spheres

Let M be a complete non-compact Riemannian manifold with non-negative Ricci curvature and $p \in M$. Show that there is $\varepsilon > 0$ such that

$$\operatorname{area}[\partial B(p,r)] > \varepsilon$$

for all sufficiently large r.

Curvature hollow

Construct a Riemannian metric on $\mathbb{R}^3$ which is Euclidean outside of an open bounded set Ω and with negative scalar curvature in Ω.

Flat coordinate planes

Let g be a Riemannian metric on $\mathbb{R}^3$, such that the coordinate planes $x = 0$, $y = 0$ and $z = 0$ are flat and totally geodesic. Assume the sectional curvature of g is either non-negative or non-positive. Show that in both cases g is flat.

Two-convexity$^\sharp$

An open subset V with smooth boundary in the Euclidean space is called *two-convex* if at most one principle curvatures in the outward direction to V is negative.

The two-convexity of V is equivalent to the following property: assume a closed curve γ lies in V and in the plane Π, if γ is contactable in V then it is contactable in $\Pi \cap V$.

Let K be a closed set bounded by a smooth surface in $\mathbb{R}^4$. Assume K contains two coordinate planes

$$\{(x,y,0,0) \in \mathbb{R}^4\} \quad \textit{and} \quad \{(0,0,z,t) \in \mathbb{R}^4\}$$

in its interior and also belongs to the closed 1-neighborhood of these two planes.

Show that the complement of K is not two-convex.

Semisolutions

Geodesic hypersurface. Let Σ be the totally geodesic embedded hypersurface in the positively curved manifold M. Without loss of generality, we can assume that Σ is connected.[1]

The complement $M\backslash\Sigma$ has one or two connected components. First let us show that if the number of connected components is two, then M is homeomorphic to a sphere.

By cutting M along Σ we get two manifolds with geodesic boundaries. It is sufficient to show that each of them is homeomorphic to a Euclidean ball.

Fix one of these manifolds, and denote it by N; denote by $f\colon N\to\to\mathbb{R}$ the distance functions to the boundary ∂N. By Riccati equation $\operatorname{hess} f\leqslant 0$ at any smooth point, and for any point the same holds in the barrier sense [defined on page 30]. It follows that f is concave.

Fix a compact subset K in the interior of N and smooth $\varphi\circ f$ in a neighborhood of K keeping it concave. This can be done by applying the smoothing theorem of Greene and Wu [see Theorem 2 in 69].

After the smoothing, the obtained strictly concave function, say h has single critical point which is its maximum. In particular by Morse lemma, we get that if the set

$$N_s'=\{\,x\in N\mid h(x)\geqslant s\,\}$$

is not empty and lies in K then it is diffeomorphic to a Euclidean ball.

For appropriately chosen set K and the smoothing h, the set N_s' can be made arbitrary close to N; moreover, its boundary $\partial N_s'$ can be made arbitrary close in the C^∞-metric to ∂N. It follows that N are diffeomorphic to a Euclidean ball. This finishes the proof of the first case.

Now assume $M\backslash\Sigma$ is connected. In this case there is a double cover $\tilde M$ of M which induce a double cover $\tilde\Sigma$ of Σ, so $\tilde M$ contains a geodesic hypersurface $\tilde\Sigma$ which divides $\tilde M$ into two connected components. From the case which already has been considered, $\tilde M$ is homeomorphic to a sphere; hence the second case follows. □

The problem was suggested by Peter Petersen.

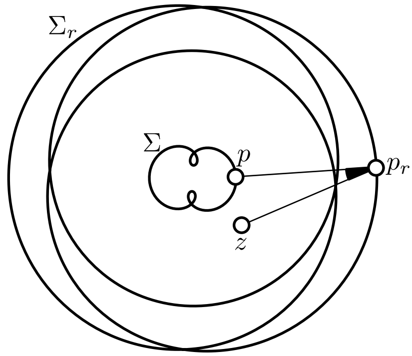
If convex, then embedded. Set

$$m=\dim\Sigma=\dim M-1.$$

Given a point in p on Σ denote by p_r the point on distance r from p which lies on the geodesic starting from p in the outer normal

[1] In fact, by Frankel's theorem [see page **??**] Σ is connected.

direction to Σ. Note that for fixed $r \geqslant 0$, the points p_r sweep an immersed locally convex hypersurface which we denote by Σ_r.



Fix $z \in M$. Denote by d the maximal distance from z to the points in Σ. Note that any point on Σ_r lies on a distance at least $r - d$ from z.

By comparison,

$$\measuredangle[p_r\,{}^{z}_{p}] \leqslant \arcsin \tfrac{d}{r}.$$

In particular, for large r, each infinite geodesic starting at z intersects Σ_r transversally.

The space of geodesics starting from z is homeomorphic to $\mathbb{S}^m$. Therefore the map which send a point $x \in \Sigma_r$ to a geodesic from z thru x induce a local diffeomorphism $\varphi_r \colon \Sigma \to \mathbb{S}^m$.

Since $m \geqslant 2$, the sphere $\mathbb{S}^m$ is simply connected. Since Σ is connected, the map φ_r is a diffeomorphism. It follows that Σ_r is star-shaped with center at z. In particular Σ_r is embedded embedded. Since Σ_r is locally convex, it bounds a convex region.

The latter statement holds for all $r \geqslant 0$; this can be shown by applying the open-closed argument. Hence the result follows. $\square$

The problem is due to Stephanie Alexander [see 70].

Immersed ball. Equip Σ with the induced intrinsic metric. Denote by κ the lower bound for principle curvatures of Σ. Note that we can assume that $\kappa > 0$.

Fix sufficiently small $\varepsilon = \varepsilon(M, \kappa) > 0$. Given $p \in \Sigma$ denote by $\Delta(p)$ the ε-ball in Σ centered at p. Consider the lift $\tilde h_p \colon \Delta(p) \to \mathrm{T}_{h(p)}$ along the exponential map $\exp_{h(p)} \colon \mathrm{T}_{h(p)} \to M$. More precisely:

1. Connect each point $q \in \Delta(p) \subset \Sigma$ to p by a minimizing geodesic path $\gamma_q \colon [0,1] \to \Sigma$
2. Consider the lifting $\tilde\gamma_q$ in $\mathrm{T}_{h(p)}$; that is, the curve such that $\tilde\gamma_q(0) = 0$ and $\exp_{h(p)} \circ \tilde\gamma_q(t) = \gamma_q(t)$ for any $t \in [0,1]$.
3. Set $\tilde h(q) = \tilde\gamma_q(1)$.

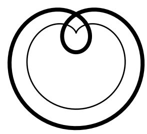
Show that all the hypersurfaces $\tilde h_p(\Delta(p)) \subset \mathrm{T}_{h(p)}$ has principle curvatures at least $\frac{\kappa}{2}$.

Use the same idea as in the solution of “Immersed surface” [page 19] to show that one can fix $\varepsilon = \varepsilon(M, \kappa) > 0$ such that the restriction of $\tilde h_p|_{\Delta(p)}$ is injective. Conclude that the restriction $h|_{\Delta(p)}$ is injective for any $p \in \Sigma$.

Now consider locally equidistant surfaces Σ_t in the inward direction for small t. The principle curvatures of Σ_t remain at least κ in the barrier sense. By the same argument as above, any ε-ball in Σ_t is embedded.

Applying open-closed argument we get a one parameter family of locally convex locally equidistant surfaces Σ_t for t in the maximal interval $[0,a]$, where the surface Σ_a degenerates to a point, say p.

To construct the immersion $\partial\bar{B}^m \looparrowright M$, take the point p as the image of the center $\bar{B}^m$ and take the surfaces Σ_t as the restrictions of the embedding to the spheres; the existence of the immersion follows from the Morse lemma. □



As you see from the picture, the analogous statement does not hold in the two-dimensional case.

The proof presented above was indicated in the lectures of Mikhael Gromov [see 47] and written rigorously by Jost Eschenburg in [71].

A variation of Gromov's proof was obtained independently by Ben Andrews in [72]. Instead of equidistant deformation, he uses a so called *inverse mean curvature flow*; this way one has to perform some calculations to show that convexity survives in the flow, but one does not have to worry about non-smoothness of the hypersurfaces Σ_t.

Minimal surface in the sphere. Fix a geodesic n-dimensional sphere $\tilde{\Sigma} = \mathbb{S}^n \subset \mathbb{S}^m$.

Given $r \in (0, \frac{\pi}{2}]$, denote by U_r and $\tilde{U}_r$ the closed tubular r-neighborhood of Σ and $\tilde{\Sigma}$ in $\mathbb{S}^m$ correspondingly.

Note that

$$(*) \qquad U_{\frac{\pi}{2}} = \tilde{U}_{\frac{\pi}{2}} = \mathbb{S}^m.$$

Indeed, clearly $\tilde{U}_{\frac{\pi}{2}} = \mathbb{S}^m$. If $U_{\frac{\pi}{2}} \neq \mathbb{S}^m$, fix $x \in \mathbb{S}^m \backslash U_r$. Choose a closest point $y \in \Sigma$ to x. Since $r = |x-y|_{\mathbb{S}^m} > \frac{\pi}{2}$ the r-sphere $\mathrm{S}_r \subset \mathbb{S}^m$ with center x is concave. Note that S_r supports Σ at y; in particular the mean curveture vector of Σ at y can not vanish, a contradiction.

By Riccati equation,

$$H_r(x) \geqslant \tilde{H}_r$$

for any $x \in \partial U_r$, where $H_r(x)$ denotes the mean curvature of ∂U_r at a point x and $\tilde{H}_r$ is the mean curvature of $\partial\tilde{U}_r$, the latter is the same at all points.

Set

$$a(r) = \mathrm{vol}_{m-1}\,\partial U_r, \qquad \tilde{a}(r) = \mathrm{vol}_{m-1}\,\partial\tilde{U}_r,$$
$$v(r) = \mathrm{vol}_m\,U_r, \qquad \tilde{v}(r) = \mathrm{vol}_m\,\tilde{U}_r.$$

by the coarea formula,

$$\tfrac{d}{dr}v(r) \overset{a.e.}{=\!=} a(r), \qquad\qquad \tfrac{d}{dr}\tilde v(r) = \tilde a(r).$$

Note that

$$\begin{aligned}\tfrac{d}{dr}a(r) &\leqslant \int\limits_{\partial U_r} H_r(x)\cdot d_x \operatorname{vol}_{m-1} \leqslant \\ &\leqslant a(r)\cdot \tilde H_r\end{aligned}$$

and

$$\tfrac{d}{dr}\tilde a(r) = \tilde a(r)\cdot \tilde H_r.$$

It follows that

$$\frac{v''(r)}{v(r)} \leqslant \frac{\tilde v''(r)}{\tilde v(r)}$$

for almost all r. Therefore

$$v(r) \leqslant \frac{\operatorname{area}\Sigma}{\operatorname{area}\tilde\Sigma}\cdot\tilde v(r)$$

for any $r > 0$.

According to $(*)$,

$$v(\tfrac{\pi}{2}) = \tilde v(\tfrac{\pi}{2}) = \operatorname{vol}\mathbb{S}^m.$$

Hence the result follows. $\square$

This problem is the geometric part of the isoperimetric inequality proved by Frederick Almgren in [73]. The argument is similar to the proof of isometric inequality for manifolds with positive Ricci curvature given by Mikhael Gromov in [74].

Hypercurve. Fix $p \in M$. Denote by s the second fundamental form of M at p. Recall that s is a symmetric bi-linear form on the tangent space T_pM of M with values in the normal space N_pM to M, see page 33.

By Gauss formula

$$\langle R(X,Y)Y,X\rangle = \langle s(X,X), s(Y,Y)\rangle - \langle s(X,Y), s(X,Y)\rangle,$$

Since the sectional curvature of M is positive, we get

$$(*) \qquad \langle s(X,X), s(Y,Y)\rangle > 0$$

for any pair of nonzero vectors $X, Y \in \mathrm{T}_p M$.

The normal space $\mathrm{N}_p M$ is two-dimensional. By $(*)$ there is an orthonormal basis e_1, e_2 in $\mathrm{N}_p M$ such that the real-valued quadratic forms

$$s_1(X,X) = \langle s(X,X), e_1\rangle, \qquad s_2(X,X) = \langle s(X,X), e_2\rangle$$

are positive definite.

Note that the curvature operators $\mathbf{R}_1$ and $\mathbf{R}_2$, defined by the following identity

$$\mathbf{R}_i(X\wedge Y), V\wedge W\rangle = s_i(X,W)\cdot s_i(Y,V) - s_i(X,V)\cdot s_i(Y,W),$$

are positive. Finally, note that $\mathbf{R} = \mathbf{R}_1 + \mathbf{R}_2$ is the curvature operator of M at p. $\square$

The problem is due to Alan Weinstein [see 75]. Note that from [76]/[77] it follows that that the universal cover of M is homeomorphic/diffeomorphic to a standard sphere.

Horo-sphere. Set $m = \dim\Sigma = \dim M - 1$.

Let $\mathrm{bus}\colon M \to \mathbb{R}$ be the Busemann function such that $\Sigma = \mathrm{bus}^{-1}(\{0\})$. Set $\Sigma_r = \mathrm{bus}^{-1}\{r\}$, so $\Sigma_0 = \Sigma$.

Let us equip each Σ_r with induced Riemannian metric. Note that all Σ_r have bounded curvature. In particular, the unit ball in Σ_r has volume bounded above by a universal constant, say v_0.

Given $x \in \Sigma$ denote by γ_x the unit-speed geodesic such that $\gamma_x(0) = x$ and $\mathrm{bus}(\gamma_x(t)) = t$ for any t. Consider the map $\varphi_r\colon \Sigma \to \Sigma_r$ defined as $\varphi_r\colon x \mapsto \gamma_x(r)$.

Notice that φ_r is a bi-Lipschitz map with the Lipschitz constants $e^{a\cdot r}$ and $e^{b\cdot r}$. In particular, the ball of radius R in Σ is mapped by φ_r to a ball of radius $e^{a\cdot r}\cdot R$ in Σ_r. Therefore

$$\mathrm{vol}_m B(x,R)_\Sigma \leqslant e^{m\cdot b\cdot r}\cdot \mathrm{vol}_m B(\varphi_r(x), e^{a\cdot r}\cdot R)_{\Sigma_r}$$

for any $R, r > 0$. Taking $R = e^{-a\cdot r}$, we get

$$\mathrm{vol}_m B(x,R)_\Sigma \leqslant v_0\cdot R^{m\cdot\frac{b}{a}}$$

for any $R \geqslant 1$. Hence the statement follows. $\square$

The problem was suggested by Vitali Kapovitch.

There are examples of horo-spheres as above with degree of polynomial growth higher than m. For example, consider the horo-sphere Σ in the the complex hyperbolic space of real dimension 4. Clearly $m = \dim\Sigma = 3$, but the degree of its volume growth is 4.

In this case Σ is isometric to the Heisenberg group[2] defined below with a left-invariant metric. It instructive to show that any such metric has volume growth of degree 4.

Minimal spheres. Assuming contrary, we can choose a pair of sufficiently close minimal spheres Σ and Σ' in the 4-dimesional manifold M; we can assume that the distance a between Σ and Σ' is strictly smaller than the injectivity radius of the manifold. Note that in this case there is a unique bijection $\Sigma \to \Sigma'$, denoted by $p \mapsto p'$ such that the distance $|p - p'|_M = a$ for any $p \in \Sigma$.

Let $\iota_p \colon \mathrm{T}_p \to \mathrm{T}_{p'}$ be the parallel translation along the (necessary unique) minimizing geodesic from p to p'. Note that there is a pair (p, p') such that $\iota_p(\mathrm{T}_p\Sigma) = \mathrm{T}_{p'}\Sigma'$. Indeed, if this is not the case, then $\iota_p(\mathrm{T}_p\Sigma) \cap \mathrm{T}_{p'}\Sigma'$ forms a continuous line distribution over Σ'. Since Σ' is a two-sphere, the latter contradicts the hairy ball theorem.

Consider pairs of unit-speed geodesics α and α' in Σ and Σ' which start at p and p' correspondingly and go in the parallel directions, say ν and ν'. Set $\ell_\nu(t) = |\alpha(t) - \alpha'(t)|$.

Use the second variation formula together with the lower bound on Ricci curvature to show that $\ell_\nu''(0)$ has negative average for all tangent directions ν to Σ at p. In particular $\ell_\nu''(0) < 0$ for a vector ν as above; consider the corresponding pair α and α'. It follows that there are points $v = \alpha(\varepsilon) \in \Sigma$ near p and $v' = \alpha'(\varepsilon) \in \Sigma'$ near p' such that

$$|v - v'| < |p - p'|,$$

a contradiction. □

Likely, any compact positively curved 4-dimensional manifold cannot contain a pair of equidistant spheres. The argument above implies that the distance between such a pair has to exceed the injectivity radius of the manifold.

The problem was suggested by Dmitri Burago. Here is a short list of classical problems with use second variation formula in similar fission:

📖 *Any compact even-dimensional orientable manifold with positive sectional curvature is simply connected.*

This is called Synge's lemma [see 78].

---

[2] *Heisenberg group* is the group of 3×3 upper triangular matrices of the form

$$\begin{pmatrix} 1 & a & c \\ 0 & 1 & b \\ 0 & 0 & 1 \end{pmatrix}$$

under the operation of matrix multiplication.

Any two compact minimal hypersurfaces in a Riemannian manifold with positive Ricci curvature must intersect.

Assume Σ_1 and Σ_2 be two compact geodesic submanifolds in a manifold with positive sectional curvature M and

$$\dim\Sigma_1+\dim\Sigma_2\geqslant\dim M.$$

Show that $\Sigma_1\cap\Sigma_2\neq\varnothing$.

These two statements proved by Theodore Frankel [see 79].

Let (M,g) be a closed Riemannian manifold with negative Ricci curvature. Prove that (M,g) does not admit an isometric $\mathbb{S}^1$-action.

This is a theorem of Salomon Bochner [see 80].

The problem "Geodesic immersion" [page 30] can be considered as further development of the idea.

Positive curvature and symmetry. Let M be a 4-dimensional Riemannian manifold with isometric $\mathbb{S}^1$-action. Consider the quotient space $X=M/\mathbb{S}^1$. Note that X is a positively curved 3-dimensional Alexandrov space. In particular the angle $\measuredangle[x\,{}^{y}_{z}]$ between any two geodesics $[xy]$ and $[xz]$ is defined. Further, for any non-degenerate triangle $[xyz]$ formed by the minimizing geodesics $[xy]$, $[yz]$ and $[zx]$ in X we have

$$(*)\qquad \measuredangle[x\,{}^{y}_{z}]+\measuredangle[y\,{}^{z}_{x}]+\measuredangle[z\,{}^{x}_{y}]>\pi.$$

Assume $p\in X$ corresponds to a fixed point $\bar p\in M$ of $\mathbb{S}^1$-action. Each direction of geodesic starting from p in X corresponds to $\mathbb{S}^1$-orbit of the induced isometric action $\mathbb{S}^1\curvearrowright\mathbb{S}^3$ on the sphere of unit vectors at $\bar p$. Any such action is conjugate to the action $\mathbb{S}^1_{p,q}\curvearrowright\mathbb{S}^3\subset\mathbb{C}^2$ induced by complex matrices $\left(\begin{smallmatrix} z^p & 0\\ 0 & z^q\end{smallmatrix}\right)$ with $|z|=1$ and some relatively prime positive integers p,q. The possible quotient spaces $\Sigma_{p,q}=\mathbb{S}^3/\mathbb{S}^1_{p,q}$ have diameter $\frac{\pi}{2}$ and perimeter of any triangle in $\Sigma_{p,q}$ is at most π; this is straightforward but requires work.

It follow that for any three geodesics $[px]$, $[py]$ and $[pz]$ in X we have

$$(**)\qquad \measuredangle[p\,{}^{x}_{y}]+\measuredangle[p\,{}^{y}_{z}]+\measuredangle[p\,{}^{z}_{x}]\leqslant\pi.$$

and

$$(\substack{*\\**})\qquad \measuredangle[p\,{}^{x}_{y}],\ \measuredangle[p\,{}^{y}_{z}],\ \measuredangle[p\,{}^{z}_{x}]\leqslant\tfrac{\pi}{2}.$$

Arguing by contradiction, assume that there are 4 fixed points q_1, q_2, q_3 and q_4. Connect each pair by a minimizing geodesic $[q_iq_j]$.

Denote by ω the sum of all 12 angles of the type $\measuredangle[q_i\,{}^{q_j}_{q_k}]$. By $({}^{*}_{**})$, each triangle $[q_iq_jq_k]$ is non-degenerate. Therefore by $(*)$, we have

$$\omega > 4{\cdot}\pi.$$

Applying $(**)$ at each vertex q_i, we have

$$\omega \leqslant 4{\cdot}\pi,$$

a contradiction. □

The problem is due to Wu-Yi Hsiang and Bruce Kleiner [see 81]. The connection of this proof to Alexandrov geometry was noticed by Karsten Grove in [82]. An interesting new twist of the idea is given by Karsten Grove and Burkhard Wilking in [83].

Energy minimizer. Denote by $\mathcal{U}$ the unit tangent bundle over $\mathbb{RP}^m$ and by $\mathcal{L}$ the space of projective lines in $\ell\colon \mathbb{RP}^1 \to \mathbb{RP}^m$. The spaces $\mathcal{U}$ and $\mathcal{L}$ have dimensions $2{\cdot}m-1$ and $2{\cdot}(m-1)$ correspondingly.

According to Liouville's theorem on phase volume, the identity

$$\int\limits_{\mathcal{U}} f(v){\cdot}d_v\operatorname{vol}_{2\cdot m-1} = \int\limits_{\mathcal{L}} d_\ell\operatorname{vol}_{2\cdot(m-1)}\cdot\int\limits_{\mathbb{RP}^1} f(\ell'(t)){\cdot}dt$$

holds for any integrable function $f\colon \mathcal{U}\to\mathbb{R}$.

Let $F\colon \mathbb{RP}^m\to\mathbb{RP}^m$ be a smooth map. Note that up to a multiplicative constant, the energy of F can be expressed the following way

$$\int\limits_{\mathcal{U}} |dF(v)|^2{\cdot}d_v\operatorname{vol}_{2m-1} = \int\limits_{\mathcal{L}} d_\ell\operatorname{vol}_{2\cdot(m-1)}\cdot\int\limits_{\mathbb{RP}^1} |[d(F\circ\ell)](t)|^2{\cdot}dt.$$

The result follows since

$$\int\limits_{\mathbb{RP}^1} |[d(F\circ\ell)](t)|^2{\cdot}dt \geqslant \pi$$

for any line $\ell\colon \mathbb{RP}^1\to\mathbb{RP}^m$. □

The problem is due to Christopher Croke [see 84]. He uses the same idea to show that the identity map on $\mathbb{CP}^m$ is energy minimizing in its homotopy class. For $\mathbb{S}^m$, an analogous statement does not hold if $m\geqslant 3$. In fact, if a closed Riemannian manifold M has dimension at least 3 and $\pi_1M=\pi_2M=0$, then the identity map on M is homotopic to a map with arbitrary small energy; the latter was shown by Brian White in [85].

The same idea is used to prove Loewner's inequality on the volume in of $\mathbb{RP}^m$ with metric conformally equivalent to the canonical one [see

86]. Among the other applications, the sharp isoperimetric inequality for 4-dimensional Hadamard manifolds; it was proved by Christopher Croke in [87], see also [88].

Curvature vs. injectivity radius. We will show that if the injectivity radius of the manifold (M, g) is at least π, then the average of sectional curvatures on (M, g) is at most 1. This is equivalent to the problem.

Fix a point $p \in M$ and two orthonormal vectors $U, V \in \mathrm{T}_p M$. Consider the geodesic γ in M such that $\gamma'(0) = U$.

Set $U_t = \gamma'(t) \in \mathrm{T}_{\gamma(t)}$ and let $V_t \in \mathrm{T}_{\gamma(t)}$ be the parallel translation of $V = V_0$ along γ.

Consider the field $W_t = \sin t \cdot V_t$ on γ. Set

$$\begin{aligned} \gamma_\tau(t) &= \exp_{\gamma(t)}(\tau \cdot W_t), \\ \ell(\tau) &= \mathrm{length}(\gamma_\tau|_{[0,\pi]}), \\ q(U, V) &= \ell''(0). \end{aligned}$$

Note that

$$(*) \qquad q(U, V) = \int_0^\pi [(\cos t)^2 - K(U_t, V_t) \cdot (\sin t)^2] \cdot dt,$$

where $K(U, V)$ is the sectional curvature in the direction spanned by U and V.

Since any geodesics of length π is minimizing, we get $q(U, V) \geqslant 0$ for any pair of orthonormal vectors U and V. It follows that average value of the right hand side in $(*)$ is non-negative.

By Liouville's theorem on phase volume, while taking the average of $(*)$, we can switch the order of integrals; therefore

$$0 \leqslant \tfrac{\pi}{2} \cdot (1 - \bar{K}),$$

where $\bar{K}$ denotes the average of sectional curvatures on (M, g). Hence the result follows. □

The problem illustrates the idea of Eberhard Hopf [see 89] which was developed further by Leon Green in [90]. Hopf used it to show that a metric on torus without conjugate points must be flat and Green showed that average of sectional curvature on closed manifold without conjugate points can not be positive.

More applications of Liouville's theorem on phase volume discussed in the comments the solution of "Energy minimizer", page 45.

Almost flat manifold. An example can be found among solve manifolds; that is, quotients of solvable lie group by a lattice. In fact torus bundles over circle circles are sufficient.

A torus bundle $\mathbb{T}^m \to E \to \mathbb{S}^1$ is obtained by taking $\mathbb{T}^m \times [0,1]$ and gluing $\mathbb{T}^m \times 0$ to $\mathbb{T}^m \times 1$ along the map given by a matrix $A \in \mathrm{SL}(\mathbb{Z}, n)$.

The matrix A has to meet two conditions.

On one hand, we need to make sure that the fundamental group of E does not contain a nilpotent group of finite index. This can be achieved by making at least one of eigenvalues of A different from 1 by absolute value.

On the other hand the space E has to admit a metric with small curvature and diameter, this can be achieved by making all eigenvalues of A close enough to 1 by absolute value. So the $n{\times}n$ matrix

$$A = \begin{pmatrix} 0 & 0 & \dots & 0 & 1 & 1 \\ 1 & 0 & \dots & 0 & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ 0 & 0 & \dots & 0 & 0 & 0 \\ 0 & 0 & \dots & 1 & 0 & 0 \\ 0 & 0 & \dots & 0 & 1 & 0 \end{pmatrix}.$$

for large enough n does the job; its characteristic polynomial is

$$x^n - x + 1. \qquad \square$$

This example was constructed by Galina Guzhvina [see 91].

It is expected that for small enuf $\varepsilon > 0$, a Riemannian manifold (M, g) of any dimension with $\operatorname{diam}(M, g) \leqslant 1$ and $|K_g| \leqslant \varepsilon$ cannot be simply connected, here K_g denotes the sectional curvature of g.

The latter does not hold with the condition $K_g \leqslant \varepsilon$ instead. In fact, for any $\varepsilon > 0$, there is a metric g on $\mathbb{S}^3$ with $K_g \leqslant \varepsilon$ and $\operatorname{diam}(\mathbb{S}^3, g) \leqslant 1$. This example was originally constructed by Mikhael Gromov in [66]; a simplified proof was given by Peter Buser and Detlef Gromoll in [92].

Approximation of a quotient. Note that G admits an embedding into a compact connected Lie group H; in fact we can assume that $H = \mathrm{SO}(n)$, for large enuf n.

Fix a $\kappa \leqslant 0$ such that the curvature bound of (M, g) is bounded below by κ.

The bi-invariant metric h on H is non-negatively curved. Therefore for any positive integer n the product $(H, \frac{1}{n}\cdot h) \times (M, g)$ is a Riemannian manifold with curvature bounded below by κ.

The diagonal action of G on $(H, \frac{1}{n}\cdot h) \times (M, g)$ is isometric and free. Therefore the quotient $(H, \frac{1}{n}\cdot h) \times (M, g)/G$ is a Riemannian manifold, say (N, g_n). By O'Nail's formula, (N, g_n) has curvature bounded below by κ.

It remains to observe that (N, g_n) converges to $(M, g)/G$ as $n \to \infty$. □

This construction is called sometimes *Cheeger's trick*. The earliest use of it I found it [93]; it was used there to show that Berger's spheres have positive curvature. This trick is used in the constructions of most of the known examples of positively and non-negatively curved manifolds [see 94–98].

The quotient space $(M, g)/G$ has finite dimension and curvature bounded below in the sense of Alexandrov. It is expected that not all finite dimensional Alexandrov spaces admit approximation by Riemannian manifolds with curvature bounded below, some partial results are discussed in [99, 100].

Polar points. Fix a unit-speed geodesic γ which starts at p; that is, $\gamma(0) = p$. Set $p^* = \gamma(\pi)$.

Applying Toponogov comparison theorem for the triangle $[pp^*x]$, we get

$$|p^* - x'|_g + |p - x'|_g > \pi.$$

That is, p^* is a solution. □

Alternative proof. Assume the contrary; that is, for any $x \in M$ there is a point x' such that

$$|x - x'|_g + |p - x'|_g > \pi.$$

Given $x \in M$ denote by $f(x)$ a point such that

$$|x - f(x)|_g + |p - f(x)|_g$$

takes the maximal value. Show that the f is uniquely defined and continuous.

Fix sufficiently small $\varepsilon > 0$. Prove that the set $W_\varepsilon = M \backslash B(p, \varepsilon)$ is homeomorphic to a ball and the map f sends W_ε into itself.

By Brouwer's fixed-point theorem, $x = f(x)$ for some x. In this case

$$\begin{aligned}|x - f(x)|_g + |p - f(x)|_g = |p - x|_g \leqslant \\ \leqslant \pi,\end{aligned}$$

a contradiction. □

The problem is due to Anatoliy Milka [see 101].

Isometric section. Arguing by contradiction, assume there is an isometric section $\iota\colon M \to W$. It makes possible to treat M as a submanifold in W.

Given $p \in M$, denote by N_p^1 the unit normal space to M at p. Given $v \in \mathrm{N}_p^1$ and real value k, set

$$p^{k\cdot v} = s \circ \exp_p(k\cdot v).$$

Note that

$$(*) \qquad p^{0\cdot v} = p \quad \text{for any} \quad p \in M \quad \text{and} \quad v \in \mathrm{N}_p^1.$$

Fix sufficiently small $\delta > 0$. By Rauch comparison, if $w \in \mathrm{N}_q^1$ is the parallel translation of $v \in \mathrm{N}_q^1$ along a minimizing geodesic from p to q in M, then

$$(**) \qquad |p^{k\cdot v} - q^{k\cdot w}|_M < |p - q|_M$$

assuming $|k| \leqslant \delta$. The same comparison implies that

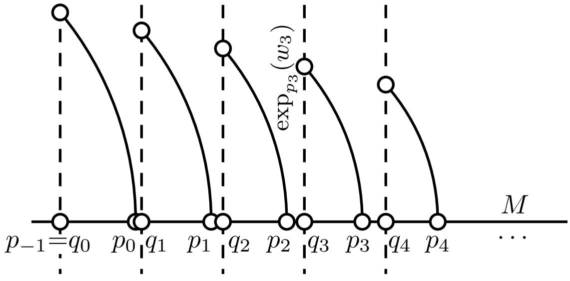
$$({}^{\,*}_{**}) \qquad |p^{k\cdot v} - q^{k'\cdot w}|_M^2 < |p - q|_M^2 + (k - k')^2$$

assuming $|k|, |k'| \leqslant \delta$.

Choose p and $v \in \mathrm{N}_p^1$ so that $r = |p - p^{\delta\cdot v}|$ takes the maximal possible value. From $(**)$ it follows that $r > 0$.

Let γ be the extension of the unit-speed minimizing geodesic from p_v to p; denote by v_t the parallel translation of v to $\gamma(t)$ along γ.

We can choose the parameter of γ so that $p = \gamma(0)$, $p^v = \gamma(-r)$. Set $p_n = \gamma(n\cdot r)$, so $p = p_0$ and $p^v = p_{-1}$. Fix large integer N and set $w_n = (1 - \frac{n}{N})\cdot v_{n\cdot r}$ and $q_n = p_n^{w_n}$.



From $({}^{\,*}_{**})$, there is a constant C independent of N such that

$$|q_k - q_{k+1}| < r + \tfrac{C}{N^2}\cdot\delta^2.$$

Therefore

$$|q_{k+1} - p_{k+1}| > |q_k - p_k| - \tfrac{C}{N^2}\cdot\delta^2.$$

By induction, we get

$$|q_N - p_N| > r - \tfrac{C}{N}\cdot\delta^2.$$

Since N is large we get

$$|q_N - p_N| > 0.$$

Note that $w_N = 0$; therefore by $(*)$, we get $q_N = p_N^0 = p_N$, a contradiction. $\square$

This is the core of the solution of Soul conjecture by Grigori Perelman [see 102].

Warped product. Given $x \in \Sigma$, denote by ν_x the normal vector to Σ at x which agrees with the orientations of Σ and M. Denote by κ_x the non-negative principle curvature of Σ at x; since Σ is minimal the other principle curvature has to be $-\kappa_x$.

Consider the warped product $W = \mathbb{S}^1 \times_f \Sigma$ for some positive smooth function $f\colon \Sigma \to \mathbb{R}$. Assume that a point $y \in W$ projects to a point $x \in \Sigma$. Straightforward computations show that

$$\begin{aligned}\mathrm{Sc}_W(y) &= \mathrm{Sc}_\Sigma(x) - 2\cdot\frac{\Delta f(x)}{f(x)} = \\ &= \mathrm{Sc}_M(x) - 2\cdot\mathrm{Ric}(\nu_x) - 2\cdot\kappa_x^2 - 2\cdot\frac{\Delta f(x)}{f(x)},\end{aligned}$$

where Sc and Ric denote the scalar and Ricci curvature correspondingly.

Consider linear operator L on the space of smooth functions on Σ defined as

$$(Lf)(x) = -[\mathrm{Ric}(\nu_x) + \kappa_x^2]\cdot f(x) - (\Delta f)(x)$$

It is sufficient to find a smooth function f on Σ such that

$$(*) \qquad f(x) > 0 \quad\text{and}\quad (Lf)(x) \geqslant 0$$

for any $x \in \Sigma$.

Fix a smooth function $f\colon \Sigma \to \mathbb{R}$. Extend the field $f(x)\cdot\nu_x$ on Σ to a smooth field, say v, on whole M. Denote by ι_t the flow along v for time t and set $\Sigma_t = \iota_t(\Sigma)$.

Informal end of proof. Denote by $H_t(x)$ the mean curvature of Σ_t at $\iota_t(x)$. Note that the value $(Lf)(x)$ is the derivative of the function $t \mapsto H_t(x)$ at $t = 0$.

Therefore the condition $(*)$ means that we can push Σ into one of its sides so that its mean curvature does not increase in the first order. Since Σ is area minimizing, the existence of such push follows; read further if you are not convinced. $\square$

Formal end of proof. Denote by $\delta(f)$ the second variation of area of Σ_t; that is, consider the area function $a(t) = \operatorname{area}\Sigma_t$ and set $\delta(f) = a''(0)$. Direct calculations show that

$$\begin{aligned}\delta(f) &= \int\limits_{\Sigma} \left(-[\operatorname{Ric}(\nu_x) + \kappa_x^2]\cdot f^2(x) + |\nabla f(x)|^2\right)\cdot d_x \operatorname{area} = \\ &= \int\limits_{\Sigma} (Lf)(x)\cdot f(x)\cdot d_x \operatorname{area}.\end{aligned}$$

Since Σ is area minimizing we get

$$(**) \qquad \delta(f) \geqslant 0$$

for any f.

Choose a function f which minimize $\delta(f)$ among all the functions such that $\int_\Sigma f^2(x)\cdot d_x \operatorname{area} = 1$. Note that f an eigenfunction for the linear operator L; in particular f is smooth. Denote by λ the eigenvalue of f; by $(**)$, $\lambda \geqslant 0$.

Show that $f(x) > 0$ at any x. Since $Lf = \lambda\cdot f$, the inequalities $(*)$ follow. □

The problem is due to Mikhael Gromov and Blaine Lawson [see 103]. Earlier in [104], Shing-Tung Yau and Richard Schoen showed that the same assumptions imply existence of conformal factor on Σ which makes it positively curved. Both statement are used the same way to proof that $\mathbb{T}^3$ does not admit a metric with positive scalar curvature.

Both statements admit straightforward generalization to higher dimensions and they can be used to show non existence metric with positive scalar curvature on $\mathbb{T}^m$ with $m \leqslant 7$. For $m = 8$, the proof stops to work since in this dimension the area minimizing hypersurfaces might have singularities. For example, any domain in the cone in $\mathbb{R}^8$ defined by the identity

$$x_1^2 + x_2^2 + x_3^2 + x_4^2 = x_5^2 + x_6^2 + x_7^2 + x_8^2$$

is area minimizing among the hypersurfaces with the same boundary.

No approximation. Fix an increasing function $\varphi\colon (0, r) \to \mathbb{R}$ such that

$$\varphi'' + (n-1)\cdot(\varphi')^2 + C = 0.$$

If $\operatorname{Ric}_{g_n} \geqslant C$, then the function $x \mapsto \varphi(|q - x|_{g_n})$ is subharmonic. Therefore for arbitrary array of points q_i and positive reals λ_i the function $f_n\colon M_n \to \mathbb{R}$ defined by the formula

$$f(x) = \sum_i \lambda_i\cdot\varphi(|q_i - x|_M)$$

is subharmonic. In particular f_n cannot admit a local minima in M_n.

Passing the limit as $n \to \infty$, we get that any function $f\colon \mathbb{R}^m \to \mathbb{R}$ of the form

$$f(x) = \sum_i \lambda_i \cdot \varphi(|q_i - x|_{\ell_p})$$

does not admit a local minima in $\mathbb{R}^m$.

Let e_i be the standard basis of $\mathbb{R}^m$. If $p < 2$, then straightforward calculation show that

$$f(x) = \sum \varphi(|q - x|_{\ell_p})$$

where the sum is taken for all $q = \pm\varepsilon\cdot e_i$, has strict local minimum at 0 and $\varepsilon > 0$ is small. If $p > 2$, one has to take the same sum for $p =\sim_i \pm\varepsilon\cdot e_i$ for all choices of signs. In both case we get a contradiction. □

The argument given here is very close to the proof of Abresch–Gromoll inequality in [105]. The solution admits a straightforward generalization which imples that if an m-dimensional Finsler manifold F is a Gromov–Hausdorff limit of m-dimensional Riemannian manifolds with uniform lower bound on Ricci curvature, then F has to be Riemannian.

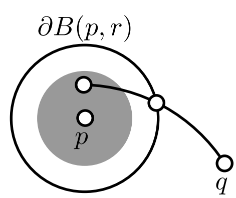
An alternative solution of this problem can be build on almost splitting theorem proved by Jeff Cheeger and Tobias Colding in [106].

Area of spheres. Fix $r_0 > 0$. Given $r > r_0$, choose a point q on the distance $2\cdot r$ from p.

Note that any minimizing geodesic from q to a point in $B(p, r_0)$ has to cross $\partial B(p, r)$. By volume comparison, we get that

$$\operatorname{vol} B(p, r_0) \leqslant C_m \cdot r_0 \cdot \operatorname{area} \partial B(p, r),$$

where C_m is a constant depending only on the dimension $m = \dim M$; say, $C_m = 10^m$ will do.



□

Applying the coarea formula, we get that volume growth of M is at least linear and in particular it has infinite volume. The latter was proved independently by Eugenio Calabi and Shing-Tung Yau [see 107, 108].

Curvature hollow. An example can be found among the metrics with isometric $\mathbb{S}^1$ action which fix a line.

First note that it is easy to construct such metric on the connected sum $\mathbb{R}^3\#\mathbb{S}^2 \times \mathbb{S}^1$. Indded make two holes in $\mathbb{R}^3$, deform the obtained space conformally so that scalar curvature drops and the two holes fit and glue the holes to each other. Further, note that such metric can be constructed in such a way that it has a closed geodesic γ with trivial holonomy and with constant negative curvature in its a tubular neighborhood.

Cut tubular neighborhood $V \simeq \mathbb{D}^2 \times \mathbb{S}^1$ of γ and glue in the product $W \simeq \mathbb{S}^1 \times \mathbb{D}^2$ with the swapped factors. Note that after this surgery we get back $\mathbb{R}^3$.

It remains to construct a metric g on W with negative scalar curvature which is identical to the original metric on V near its boundary. The needed space (W, g) can be found among wrap products $\mathbb{S}^1 \times_f \mathbb{D}^2$ [see page 36]. $\square$

This construction was given by Joachim Lohkamp in [109], he describes there yet an other equally simple construction. In fact, his constructions produce $\mathbb{S}^1$-invariant hollows with negative Ricci curvature.

On the other hand, there are no hollows with positive scalar curvature and negative sectional curvature. The former is equivalent to the positive mass conjecture [see 110, and the references therein] and the latter is an easy exercise.

Flat coordinate planes. Fix $\varepsilon > 0$ such that there is unique geodesic between any two points on distance $< \varepsilon$ from the origin of $\mathbb{R}^3$.

Consider three points a, b and c on the coordinate lines which are ε-close to the origin.

Note that the angles of the triangle $[abc]$ coincide with its model angles. The latter follows since the direction to the coordinate planes are parallel along the coordinate lines; therefore the corresponding triangle in the Euclidean coordinate space has the same angles.

Both curvature conditions imply that there is a solid flat geodesic triangle in $(\mathbb{R}^3, g)$ with vertex at a, b and c.

Use the family of constructed flat triangles to show that at any x point in the $\frac{\varepsilon}{10}$-neighborhood of the origin the sectional curvature vanish in an open set of sectional directions. The latter implies that the curvature is identically zero in this neighborhood.

Moving the origin and apply the same argument we get that the curvature is identically zero everywhere. $\square$

This problem is based on a lemma discovered by Sergei Buyalo in [Lemma 5.8 in 111, 112, see also] appears in the paper of Dmitri Panov and me [see 112]; it

Two-convexity. *Morse-style solution.* Equip $\mathbb{R}^4$ with coordinates (x, y, z, t).

Consider a generic linear function $\ell\colon \mathbb{R}^4 \to \mathbb{R}$ which is close to the sum of coordinates $x+y+z+t$. Note that ℓ has non-degenerate critical points on ∂K and all its critical values are different.

Consider the sets

$$W_s = \left\{\, w \in \mathbb{R}^4 \backslash K \;\middle|\; \ell(w) < s \,\right\}.$$

Note that W_{-1000} contains a closed curve, say α, which is contactable in $\mathbb{R}^4 \backslash K$, but not constructible in the set W_{-1000}.

Set s_0 to be the infimum of the values s such that the α is contactable in W_s.

Note that s_0 is a critical value of ℓ on ∂K; denote by p_0 the corresponding critical point. By 2-convexity of $\mathbb{R}^4 \backslash K$, the index of p_0 has to be at most 1. On the other hand, since the disc hangs at this point, its index has to be at least 2, a contradiction. □

Alexandrov-style proof. Note that two-convexity is preserved under linear transformation. Apply a linear transformation of $\mathbb{R}^4$ which makes the coordinate planes Π_1 and Π_2 not orthogonal.

Assume that the complement of K is two-convex. According to the main result of Alexander Bishop and Berg in [113], $W = \mathbb{R}^4 \backslash (\operatorname{Int} K)$ has non-positive curvature in the sense of Alexandrov. In particular the universal cover of $\tilde{W}$ of W is a CAT[0] space.

By rescaling $\tilde{W}$ and passing to the limit we obtain that universal Riemannian cover Z of $\mathbb{R}^4$ branching in the planes Π_1 and Π_2 is a CAT[0] space.

Note that Z is isometric to the Euclidean cone over universal cover Σ of $\mathbb{S}^3$ branching in two great circles $\Gamma_i = \mathbb{S}^3 \cap \Pi_i$ which are not orthogonal. The shortest path in $\mathbb{S}^3$ between Γ_1 and Γ_2 traveled 4 times back and forth is shorter than $2{\cdot}\pi$ and it lifts to closed geodesic in Σ. It follows that Σ is not CAT[1] and therefore Z is not CAT[0], a contradiction. □

The Morse-style proof is based on the idea of Mikhael Gromov [see 47, §$\tfrac{1}{2}$], where two-convexity was introduced.

Note that the 1-neighborhood of these two planes has two-convex complement W in the sense of the second definition; that is, if a closed curve γ lies in the plane Π and contactable in W then it is contactable in $\Pi \cap W$. Clearly the boundary of this neighborhood is not smooth and as it follows from the problem, it cannot be smoothed in the class of two-convex sets.

Two-convexity also shows up as the zero curvature set in the manifolds of nonnegative or nonpositive curvature is two-convex [see 112].

Chapter 4

Curvature free differential geometry

The reader should be familiar with the notion of smooth manifold, Riemannian metric and symplectic form.

Distant involution

🕮 *Construct a Riemannian metric g on $\mathbb{S}^3$ and an involution $\iota\colon \mathbb{S}^3 \to$ $\to \mathbb{S}^3$ such that* $\mathrm{vol}(\mathbb{S}^3, g)$ *is arbitrary small and*

$$|x - \iota(x)|_g > 1$$

for any $x \in \mathbb{S}^3$.

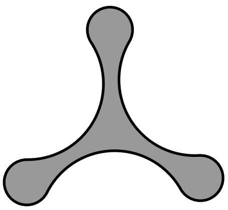
Semisolution. Given $\varepsilon > 0$, construct a disc Δ in the plane with

$$\operatorname{length}\partial\Delta < 10 \quad\text{and}\quad \operatorname{area}\Delta < \varepsilon$$

which admits an continuous involution ι such that

$$|\iota(x) - x| \geqslant 1$$

for any $x \in \partial\Delta$. An example of Δ can be guessed from the picture.



Take the product $\Delta \times \Delta \subset \mathbb{R}^4$; it is homeomorphic to the 4-ball. Note that

$$\mathrm{vol}_3[\partial(\Delta \times \Delta)] = 2\cdot \operatorname{area}\Delta\cdot \operatorname{length}\partial\Delta < 20\cdot\varepsilon.$$

The boundary $\partial(\Delta \times \Delta)$ homeomorphic to $\mathbb{S}^3$ and the restriction of the involution $(x, y) \mapsto$ $\mapsto (\iota(x), \iota(y))$ has the needed property.

It remains to smooth $\partial(\Delta\times\Delta)$ slightly. □

This example is given by Christopher Croke in [114].

It is instructive to show that for $\mathbb{S}^2$ such thing is not possible. Note also, that according to Gromov's systolic inequality [see 86], the involution ι above cannot be made isometric.

Besikovitch inequality

Let g be a Riemannian metric on an m-dimensional cube Q such that any curve connecting opposite faces has length at least 1. Prove that $\operatorname{vol}(Q,g)\geqslant 1$, and the equality holds if and only if (Q,g) is isometric to the unit cube.

Minimal foliation$^+$

The minimal surface in Riemannian manifolds are defined on page 32.

Consider $\mathbb{S}^2\times\mathbb{S}^2$ equipped with a Riemannian metric g which is C^∞-close to the product metric. Prove that there is a conformally equivalent metric $\lambda\cdot g$ and re-parametrization of $\mathbb{S}^2\times\mathbb{S}^2$ such that for any $x\in\mathbb{S}^2$, the spheres $x\times\mathbb{S}^2$ and $\mathbb{S}^2\times x$ are minimal surfaces in $(\mathbb{S}^2\times\mathbb{S}^2,\lambda\cdot g)$.

The expected solution requires pseudo-holomorphic curves introduced by Mikhael Gromov in [115].

Volume and convexity$^+$

A function f defined on Riemannian manifold is called convex if for any geodesic γ, the composition $f\circ\gamma$ is a convex real-to-real function.

Let M be a complete Riemannian manifold which admits a non-constant convex function. Prove that M has an infinite volume.

The expected solution use Liouville's theorem on phase volume. It implies in particular, that geodesic flow on the unit tangent bundle to a Riemannian manifold preserves the volume.

Sasaki metric

Let (M,g) be a Riemannian manifold. The Sasaki metric is a natural choice of Riemannian metric $\hat g$ on the total space of the tangent bundle $\tau\colon \mathrm{T}M\to M$. It is uniquely defined by the following properties:

◇ The map $\tau\colon(\mathrm{T}M,\hat g)\to(M,g)$ is a Riemannian submersion.

◇ The metric on each tangent space $\mathrm{T}_p \subset \mathrm{T}M$ is the Euclidean metric induced by g.

◇ Assume $\gamma(t)$ is a curve in M and $v(t) \in \mathrm{T}_{\gamma(t)}$ is a parallel vector field along γ. Note that $v(t)$ forms a curve in $\mathrm{T}M$. For the Sasaki metric, we have $v'(t) \perp \mathrm{T}_{\gamma(t)}$ for any t; that is, the curve $v(t)$ normally crosses the tangent spaces $\mathrm{T}_{\gamma(t)} \subset \mathrm{T}M$.

In other words, we identify the tangent space $\mathrm{T}_u[\mathrm{T}M]$ for any $u \in \mathrm{T}_pM$ with the direct sum of so called vertical and horizontal vectors $\mathrm{T}_pM \oplus \mathrm{T}_pM$. The projection of this splitting defined by the differential $d\tau\colon \mathrm{T}\mathrm{T}M \to \mathrm{T}M$ and we assume that a the velocity of a curve in $\mathrm{T}M$ formed by parallel field along a curve in M is horizontal. Then $\mathrm{T}_u[\mathrm{T}M]$ is equipped with the metric $\hat{g}$ defined as

$$\hat{g}(X, Y) = g(X^V, Y^V) + g(X^H, Y^H),$$

where $X^V, X^H \in \mathrm{T}_pM$ denotes the vertical and horizontal components of $X \in \mathrm{T}_u[\mathrm{T}M]$.

◫ *Consider the tangent bundle* $\mathrm{T}\mathbb{S}^2$ *equipped with Sasaki metric* $\hat{g}$ *induced by a Riemannian metric* g *on* $\mathbb{S}^2$*. Show that the space* $(\mathrm{T}\mathbb{S}^2, \hat{g})$ *lies on bounded distance to the ray* $\mathbb{R}_+ = [0, \infty)$ *in the sense of Gromov–Hausdorff.*

Two-systole

◫ *Given a big real number* L*, construct a Riemannian metric* g *on the 3-dimensional torus* $\mathbb{T}^3$ *such that* $\operatorname{vol}(\mathbb{T}^3, g) = 1$ *and*

$$\operatorname{area} S \geqslant L$$

for any closed surface S *which does not bound in* $\mathbb{T}^3$*.*

According to Gromov's systolic inequality [see 86], the volume of $(\mathbb{T}^3, g)$ can be bounded below in terms of its *1-systole* defined to be the least length of a noncontractible closed curve in $(\mathbb{T}^3, g)$. The lower bound on area of S as in the problem is called 2-systole of $(\mathbb{T}^3, g)$. Therefore the problem states that the Gromov's systolic inequality does not have a direct 2-dimensional analog.

Normal exponential map°

Let (M, g) be a Riemannian manifold; denote by $\mathrm{T}M$ the tangent bundle over M and by $\mathrm{T}_p = \mathrm{T}_pM$ the tangent space at point $p \in M$.

Given a vector $v \in \mathrm{T}_pM$ denote by γ_v the geodesic in (M, g) such that $\gamma(0) = p$ and $\gamma'(0) = v$. The map $\exp\colon \mathrm{T}M \to M$ defined by $v \mapsto \gamma_v(1)$ is called exponential map.

The restriction of exp to the T_p is called *exponential map at p* and denoted as $\exp_p$.

Given a smooth immersion $L \to M$; denote by $\mathrm{N}L$ the normal bundle over L. The restriction of exp to $\mathrm{N}L$ is called *normal exponential map* of L and denoted as $\exp_L$.

Let M, L be complete connected Riemannian manifolds. Assume L is immersed into M. Show that the image of the normal exponential map of L is dense in M.

Symplectic squeezing in the torus

Let

$$\omega = dx_1 \wedge dy_1 + dx_2 \wedge dy_2$$

be the standard symplectic form on $\mathbb{R}^4$. Assume $\mathbb{Z}^2$ is the integer lattice in (x_1, y_1) coordinate plane of $\mathbb{R}^4$.

Show that an arbitrary bounded domain $\Omega \subset (\mathbb{R}^4, \omega)$ admits a symplectic embedding into the quotient space $(\mathbb{R}^4, \omega)/\mathbb{Z}^2$.

Diffeomorphism test°

Let M and N be complete m-dimensional simply connected Riemannian manifolds. Assume $f\colon M \to N$ is a smooth map such that

$$|df(v)| \geqslant |v|$$

for any tangent vector v of M. Show that f is a diffeomorphism.

Volume of tubular neighborhoods$^+$

Assume M and M' be isometric closed smooth submanifolds in a Euclidean space. Show that for all small $r > 0$ we have

$$\operatorname{vol} B(M, r) = \operatorname{vol} B(M', r),$$

where $B(M, r)$ denotes the r-neighborhood of M.

Disc*

Given a big real number L, construct a Riemannian metric g on the disc $\mathbb{D}$ with

$$\operatorname{diam}(\mathbb{D}, g) \leqslant 1 \quad \textit{and} \quad \operatorname{length} \partial\mathbb{D} \leqslant 1$$

such that the boundary curve in $\mathbb{D}$ is not contractible in the class of closed curves with g-length less than L.

Shortening homotopy

📖 *Let M be a compact Riemannian manifold with diameter D and $p \in M$. Assume that for some $L > D$, there are no geodesic loops based at p in M with length in the interval $(L-D, L+D]$. Show that for any path γ_0 in (M,g) there is a homotopy γ_t rel. to the ends such that*

a) $\operatorname{length}\gamma_1 < L$;

b) $\operatorname{length}\gamma_t \leqslant \operatorname{length}\gamma_0 + 2\cdot D$ *for any* $t \in [0,1]$.

It is not at all easy to find an example of a manifold which satisfy the above condition for some L; they are found among the Zoll spheres by Florent Balachev, Christopher Croke and Mikhail Katz [see 116].

Convex hypersurface

Recall that a subset K of Riemannian manifold is called *convex* if every minimizing geodesic connecting two points in K completely lies in K.

📖 *Let M be a totally geodesic hypersurface in a closed Riemannian m-dimensional manifold W. Assume that the injectivity radius of M is at least 1 and it forms a convex set in W. Show that the maximal distance from M to the points of W can be bounded below by a positive constant ε_m which depends only on m (in fact, $\varepsilon_m = \frac{2}{m+3}$ will do).*

Note that we did not make any assumption on the injectivity radius of W.

Almost constant function

The unit tangent bundle $\mathrm{U}M$ over a closed Riemannian manifold M admits a natural choice of volume. Let us equip $\mathrm{U}M$ with the probability measure which is proportional to the volume.

We say that a unit-speed geodesic $\gamma\colon \mathbb{R} \to M$ is *random* if $\gamma'(0)$ takes the random value in $\mathrm{U}M$.

📖 *Assume $\varepsilon > 0$ is given. Show that there is a positive integer m such that for any closed m-dimensional Riemannian manifold M and any smooth 1-Lipschitz function $f\colon M \to \mathbb{R}$ the following holds.*

For a random unit-speed geodesic γ in M the event

$$|f\circ\gamma(0) - f\circ\gamma(1)| > \varepsilon$$

happens with probability at most ε.

Semisolutions

Besikovitch inequality. Without loss of generality, we may assume $Q = [0,1]^m$. Set

$$A_i = \{\ (x_1, x_2, \dots, x_m) \in Q \mid x_i = 0\,\}\,.$$

Consider functions $f_i\colon Q \to \mathbb{R}$ defined as

$$f_i(x) = \max\{1, \operatorname{dist}_{A_i}(x)\}$$

Note that each f_i is 1-Lipschitz, in particular $|\nabla f| \leqslant 1$ almost everywhere.

Consider the map

$$\boldsymbol{f}\colon x \mapsto (f_1(x), f_2(x), \dots, f_m(x)).$$

Notes that it maps Q to it self and, moreover, it maps each face of Q to it self. It follows that the restriction $\boldsymbol{f}|_{\partial Q}\colon \partial Q \to \partial Q$ has degree one and therefore $\boldsymbol{f}\colon Q \to Q$ is onto.

Assume h is the canonical metric on the cube Q. Then

$$|\mathrm{J}(x)| = |\nabla_x f_1 \wedge \dots \wedge \nabla_x f_m| \leqslant 1,$$

where $\mathrm{J}(x)$ denotes the Jacobian of the map $f\colon (Q,g) \to (Q,h)$.

By the area formula, we get

$$\begin{aligned}\operatorname{vol}(Q,g) \geqslant \int\limits_Q |\mathrm{J}(x)|\cdot d_x \operatorname{vol}_g &\geqslant \\ &\geqslant \operatorname{vol}(Q,h) = \\ &= 1\end{aligned}$$

In the case of equality we have that $\langle \nabla_x f_i, \nabla_x f_j\rangle = 0$ for $i \neq j$ and $|\nabla_x f_i| = 1$ for almost all x. It follows then that the map

$$\boldsymbol{f}\colon (Q,g) \to (Q,h)$$

is an isometry. □

This inequality was proved by Abram Besikovitch in [117]. It has number applications in Riemannian geometry. For example using this inequality it is easy to solve the following problem.

🕮 *Assume a metric g on $\mathbb{R}^m$ coincides with Euclidean outside of a bounded set K; assume further that any geodesic which comes into K*

goes out from K the same way as if the metric would be Euclidean everywhere. Show that g is flat.

Minimal foliation. The proof is based on the observation that a self-dual harmonic 2-form on $(\mathbb{S}^2\times\mathbb{S}^2, g)$ without zeros defines a symplectic structure.

Note that there is a self-dual harmonic 2-form on $(\mathbb{S}^2\times\mathbb{S}^2, g)$; that is, a 2-form ω such that $d\omega = 0$ and $\star\omega = \omega$, where $\star$ denotes the Hodge star operator. Indeed, fix a generic harmonic form φ. Note that the form $\star\varphi$ is also harmonic. Since $\star(\star\varphi) = \varphi$, the form $\omega = \varphi + \star\varphi$ does the trick.

Fix $p \in \mathbb{S}^2\times\mathbb{S}^2$. We can use g_p to identify tangent space T_p and the cotangent space T_p^*. We can choose an g_p-orthonormal basis e_1, e_2, e_3, e_4 on T_p so that

$$\omega_p = \lambda_p{\cdot}e_1\wedge e_2 + \lambda_p'{\cdot}e_3\wedge e_4.$$

Note that

$$\star\omega_p = \lambda_p'{\cdot}e_1\wedge e_2 + \lambda_p{\cdot}e_3\wedge e_4.$$

Since $\star\omega_p = \omega_p$, we have $\lambda_p = \lambda_p'$.

Consider the rotation $\mathrm{J}_p\colon \mathrm{T}_p \to \mathrm{T}_p$ defined by

$$e_1\mapsto e_2,\quad e_2\mapsto -e_1,\quad e_3\mapsto e_4,\quad e_4\mapsto -e_3.$$

Note that

$$\mathrm{J}_p\circ\mathrm{J}_p = -\mathrm{id}\quad\text{and}\quad \omega(X,Y) = \lambda_p{\cdot}g(X,\mathrm{J}_pY)$$

for any two tangent vectors $X, Y \in \mathrm{T}_p$.

Consider the canonical symplectic form ω_0 on $\mathbb{S}^2\times\mathbb{S}^2$; that is, the sum of pullbacks of the volume form on $\mathbb{S}^2$ for the two coordinate projections $\mathbb{S}^2\times\mathbb{S}^2\to\mathbb{S}^2$. Note that for the canonical metric on $\mathbb{S}^2\times\mathbb{S}^2$, the form ω_0 is harmonic and self-dual. Since g is close to the standard metric, we can assume that ω is close to ω_0. In particular $\lambda_p\ne 0$ for any $p\in\mathbb{S}^2\times\mathbb{S}^2$.

It follows that J is a pseudo-complex structure for the symplectic form ω on $\mathbb{S}^2\times\mathbb{S}^2$. The Riemannian metric $g' = \lambda{\cdot}g$ is a conformal to g and $\omega(X,Y) = g'(X,\mathrm{J}Y)$ for any two tangent vectors X, Y at one point. In this case the J-holomorphic curves are minimal with respect to g'; in fact, they are area minimizing in its homology class.

It remains to re-parametrize $\mathbb{S}^2\times\mathbb{S}^2$ so that vertical and horizontal spheres will form pseudo-holomorphic curves in the homology classes of $x\times\mathbb{S}^2$ and $\mathbb{S}^2\times y$. $\square$

For general metric the form ω might vanish at some points. If the metric is generic, then it happens on disjoint circles [see 118].

Volume and convexity. We use the idea from the proof of Poincaré recurrence theorem.

Let M be a complete Riemannian manifold which admits a convex function f. Denote by $\tau\colon \mathrm{U}M \to M$ the unit tangent bundle over M. Consider the function $F\colon \mathrm{U}M \to \mathbb{R}$ defined as $F(u) = f \circ \tau(u)$.

Note that there is a nonempty bounded open set $\Omega \subset \mathrm{U}M$ such that $df(u) > \varepsilon$ for any $u \in \Omega$ and some fixed $\varepsilon > 0$.

Denote by φ^t the geodesic flow for time t on $\mathrm{U}M$. By Liouville's theorem on phase volume, we have

$$(*) \qquad \operatorname{vol}[\varphi^t(\Omega)] = \operatorname{vol}\Omega$$

for any t.

Given $u \in \mathrm{U}M$, consider the function $h_u(t) = F \circ \varphi^t(u)$. Since f is convex, so is h_u. Therefore $h_u'(t) > \varepsilon$ for any $t \geqslant 0$ and $u \in \Omega$.

It follows that there is an infinite sequence of times

$$0 = t_0 < t_1 < t_2 < \dots$$

such that

$$h_v(t_{i-1}) < h_u(t_i)$$

for any $u, v \in \Omega$ and i. In particular, we have

$$\varphi^{t_i}(\Omega) \cap \varphi^{t_j}(\Omega) = \varnothing$$

for $i \neq j$. By $(*)$, the latter implies that $\operatorname{vol}(\mathrm{U}M) = \infty$. Hence

$$\operatorname{vol} M = \infty. \qquad \square$$

The problem is due to Richard Bishop and Barrett O'Neill [see 119], it was generalized by Shing-Tung Yau in [120].

Sasaki metric. Fix a point $p \in \mathbb{S}^2$. Note that any rotation of the tangent space $\mathrm{T}_p = \mathrm{T}_p(\mathbb{S}^2, g)$ appear as a holonomy of some loop at p; moreover the length of such loop can be bounded by some constant, say ℓ.

Indeed, fix a smooth homotopy $\gamma_t\colon [0,1] \to \mathbb{S}^2$, $t \in [0,1]$ of loops based at p which sweeps out $\mathbb{S}^2$. By Gauss–Bonnet formula, the total curvature of $(\mathbb{S}^2, g)$ is $4{\cdot}\pi$. It follows that any rotation of T_p appears as a holonomy of γ_t for some t. Therefore one can take

$$\ell = \max\{\, \operatorname{length}\gamma_t \mid t \in [0,1] \,\}.$$

Denote by d the diameter of $(\mathbb{S}^2, g)$. From above it follows that for any two unit tangent vectors $v \in \mathrm{T}_p$ and $w \in T_q$ there is a path $\gamma\colon [0,1] \to \mathbb{S}^2$ from p to q such that

$$\operatorname{length}\gamma \leqslant \ell + d$$

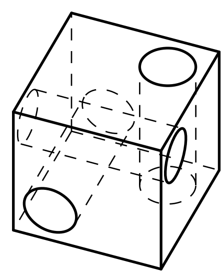
and w is the parallel transport of v along γ.

In particular, the diameter of the set of all vectors of fixed magnitude in $(\mathrm{T}\mathbb{S}^2, \hat{g})$ has diameter at most $\ell + d$. Therefore the map $\mathrm{T}\mathbb{S}^2 \to [0,\infty)$ defined as $v \mapsto |v|$ preserves the distance up to error $\ell + d$. Hence the result follows. $\square$

Two-systole. Consider the unit cube with three not intersecting cylindrical tunnels between the pairs of opposite faces.

In each tunnel, shrink the metric long-wise and expand it cross-wise while keeping the volume the same.

More precisely, assume (x, y, z) is the coordinate system on the cylindrical tunnel $\mathbb{D} \times [0,1]$ then the new metric is defined as



$$g = \varphi\cdot[(dx)^2 + (dy)^2] + \tfrac{1}{\varphi^2}\cdot(dz)^2,$$

where $\varphi = \varphi(x,y)$ is a positive smooth function on $\mathbb{D}$ which takes huge values around the center and equals to 1 near the boundary of $\mathbb{D}$.

Gluing the opposite faces of the cube, we obtain a 3-dimensional torus with a smooth Riemannian metric.

Since the surface S does not bound in $\mathbb{T}^3 = \mathbb{S}^1 \times \mathbb{S}^1 \times \mathbb{S}^1$, one of the three coordinates projections $\mathbb{T}^3 \to \mathbb{T}^2 = \mathbb{S}^1 \times \mathbb{S}^1$ induce a map of non-zero degree $S \to \mathbb{T}^2$. It follows that

$$\operatorname{area} S \geqslant \operatorname{area}(\mathbb{D}, \varphi\cdot[(dx)^2 + (dy)^2]).$$

For the right choice of function φ, the right hand side can be made bigger than the given number L. Hence the statement follows. $\square$

I learned this problem from Dmirti Burago.

Normal exponential map. Assume the contrary; that is, there is a point $p \in M$ such that the image of normal exponential map to L does not intersect the ball $B(p,\varepsilon)_M$; that is, no geodesic normal to L crosses the ball.

Fix a positive real number R such that $B(p,R)_M \cap L \neq \varnothing$. The sectional curvature of M in the ball $B(p,R)$ is bounded above by some constant, say K.

Given $q \in L$, denote by v_q the direction of a minimizing geodesic $[qp]$. Note that $v_q \notin \mathrm{N}_q L$. Moreover there is $\delta = \delta(\varepsilon, K, R) > 0$ such that for any point $q \in B(p, R)_M \cap L$, and any normal vector $n \in \mathrm{N}_q L$, we have

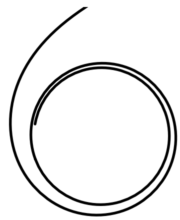
$$\measuredangle(v_q, n) > \delta.$$

Otherwise the geodesic in the direction of n would cross $B(p, \varepsilon)_M$.

It follows that starting at any point $q \in B(p, R)_M \cap L$ one can construct a unit-speed curve γ in L such that

$$|p - \gamma(t)| \leqslant |p - q| - t\cdot \sin\delta.$$

Following γ for sufficient time brings us to p; that is, $p \in L$, a contradiction. □



The problem was suggested by Alexander Lytchak.

From the picture, you should guess an example of immersion such that one point does not lie in the image of the corresponding normal exponential map. It might be interesting to understand what type of subsets can be avoided by such images.

Symplectic squeezing in the torus. The embedding will be given as a composition of a linear symplectomorphism λ with the quotient map $\varphi\colon \mathbb{R}^4 \to \mathbb{T}^2 \times \mathbb{R}^2$ by the integer (x_1, y_1)-lattice.

The composition $\varphi \circ \lambda$ always preserves the symplectic structure; it remains to find λ such that the restriction $\varphi \circ \lambda|_\Omega$ is injective.

Without loss of generality, we can assume that Ω is a ball centered at the origin. Choose an oriented 2-dimensional subspace V subspace of $\mathbb{R}^4$ such that the integral of ω over $\Omega \cap V$ is a positive number smaller than $\frac{\pi}{4}$.

Note that there is a linear symplectomorphism λ which maps planes parallel to V to planes parallel to the (x_1, y_1)-plane, and that maps the disk $V \cap \Omega$ to a round disk. It follows that the intersection of $\lambda(\Omega)$ with any plane parallel to the (x_1, y_1)-plane is a disk of radius at most $\frac{1}{2}$. In particular $\varphi \circ \lambda|_\Omega$ is injective. □

This construction is given by Larry Guth in [121] and attributed to Leonid Polterovich.

Note that according to the Gromov's non-squeezing theorem [see 115], an analogous statement with $\mathbb{C} \times \mathbb{D}$ as the target does not hold, here $\mathbb{D} \subset \mathbb{C}$ is the open disc with the induced symplectic structure. In particular, it shows that the projection of $\lambda(\Omega)$ as above to (x_1, y_1)-plane cannot be made arbitrary small.

Diffeomorphism test. Note that the map f is an open immersion.

Let h be the pullback metric on M for $f\colon M \to N$. Clearly $h \geqslant g$. In particular (M,h) is complete and the map $f\colon (M,h) \to N$ is a local isometry.

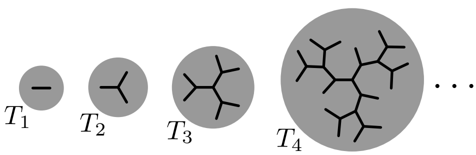
Note that any local isometry between complete connected Riemannian manifolds of the same dimension if a covering map. Since N is simply connected, the result follows. $\square$

Volume of tubular neighborhoods. This problem is a direct corollary of the so called *tube formula* given by Hermann Weyl in [122]. It express the volume of r-neighborhood of M as a polynomial $p(r)$; the coefficients of p, up to a multiplicative constant, the integrals along M of so called Lipschitz–Killing curvatures — certain scalars which can be expressed in terms of curvature tensor at the given point.

Disc. The following claim is the key step in the proof.

$(*)$ *Given a positive integer n there is a binary tree T_n embedded into the disc $\mathbb{D}$ such that any null-homotopy of $\partial\mathbb{D}$ passes thru a curve which intersects n different edges.*

The proof of the claim can be done by induction on n; the base is trivial. Assuming we constructed T_{n-1}, the tree T_n can be obtained by identifying three endpoints of three copies of T_{n-1}.



Fix $\varepsilon = \frac{1}{10}$ and a large integer n. Let us construct a metric on the disc $\mathbb{D}$ with the embedded tree T_n as in $(*)$ such that its diameter and length of its boundary below 1 and the distance between any two edges of T_n of without common vertex is at least ε.

Fix a Riemannian metric g on the cylinder $\mathbb{S}^1 \times [0,1]$ such that

- ⋄ The ε-neighborhoods of the boundary components have product metrics.
- ⋄ Any vertical segment $x \times [0,1]$ has length $\frac{1}{2}$.
- ⋄ One of the boundary component has length ε.
- ⋄ The other boundary component has length $2{\cdot}m{\cdot}\varepsilon$, where m is the number of edges in the tree T_n.

Equip T_n with a length-metric so that each edge has length ε. Glue by piecewise isometry the cylinder $(\mathbb{S}^1 \times [0,1], g)$ along its long boundary component to the tree T_n in such a way that the resulting space is homeomorphic to disc and the obtained embedding of T_n in $\mathbb{D}$ is the same as in the claim $(*)$.

By $(*)$ and the construction, for any null-homotopy of the boundary the least length exceeds $\frac{\varepsilon}{10}\cdot n = \frac{1}{100}\cdot n$. The obtained metric is not Riemannian, but is easy to smooth while keeping this property.

Since n is large the result follows. $\square$

This example was constructed by Sidney Frankel and Mikhail Katz in [123].

Shortening homotopy. Set

$$p = \gamma_0(0) \quad \text{and} \quad \ell_0 = \operatorname{length}\gamma_0.$$

By compactness argument, there exists $\delta > 0$ such that no geodesic loops based at p has length in the interval $(L - D, L + D + \delta]$.

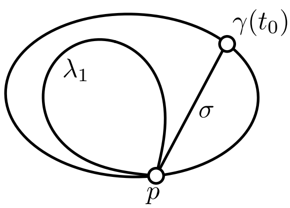
Assume $\ell_0 \geqslant L + \delta$. Choose $t_0 \in [0, 1]$ such that

$$\operatorname{length}\left(\gamma_0|_{[0,t_0]}\right) = L + \delta$$

Let σ be a minimizing geodesic from $\gamma(t_0)$ to p. Note that γ_0 is homotopic to the concatenation

$$\gamma_0' = \gamma_0|_{[0,t_0]} * \sigma * \bar\sigma * \gamma|_{[t_0,1]},$$

where $\bar\sigma$ denotes the backward parametrization of σ.



Applying a curve shortening process to the loop $\lambda_0 = \gamma|_{[0,t_0]} * \sigma$, we get a homotopy λ_t rel. its ends from the loop λ_0 to a geodesic loop λ_1 at p. From above,

$$\operatorname{length}\lambda_1 \leqslant L - D.$$

The concatenation $\gamma_t = \lambda_t * \bar\sigma * \gamma|_{[t_0,1]}$ is a homotopy from γ_0' to an other curve γ_1. From the construction it is clear that

$$\begin{aligned}\operatorname{length}\gamma_t &\leqslant \operatorname{length}\gamma_0 + 2\cdot\operatorname{length}\sigma \leqslant\\ &\leqslant \operatorname{length}\gamma_0 + 2\cdot D\end{aligned}$$

for any $t \in [0, 1]$ and

$$\begin{aligned}\operatorname{length}\gamma_1 &= \operatorname{length}\lambda_1 + \operatorname{length}\sigma + \operatorname{length}\gamma|_{[t_0,1]} \leqslant\\ &\leqslant L - D + D + \operatorname{length}\gamma - (L + \delta) =\\ &= \ell_0 - \delta.\end{aligned}$$

Repeating the procedure few times we get we get curves $\gamma_2, \gamma_3, \dots, \gamma_n$ connected by the needed homotopies so that $\ell_{i+1} \leqslant \ell_i - \delta$ and $\ell_n < L + \delta$, where $\ell_i = \operatorname{length} \gamma_i$.

If $\ell_n \leqslant L$, we are done. Otherwise repeat the argument once more for $\delta' = \ell_n - L$. □

The problem is due to Alexander Nabutovsky and Regina Rotman [see 124].

Convex hypersurface. First let us define the *cone construction* of maps into M.

Assume Δ' is a simplex and Δ is its facet opposite to the vertex v. Assume $f\colon \Delta \to M$ is a map and $x \in M$ such that $f(\Delta) \subset B(x, 1)$. Given $w \in \Delta$, let $\gamma_w\colon [0,1] \to M$ be the minimizing geodesic path from x to $f(w)$. Since the injectivity radius of M is at least 1, the path γ_w is uniquely defined. The map $f'\colon \Delta' \to M$ defined as

$$f'\colon (1-t)\cdot v + t\cdot w \mapsto \gamma_w(t)$$

is called *cone over* f with the vertex x.

One may start with a map $f_0\colon \Delta_0 \to M$ and iterate the cone construction for the vertices $x_1, \dots x_k$, to get a sequence of maps $f_i\colon \Delta_i \to M$ as far as $f_{i-1}(\Delta_{i-1}) \subset B(x_i, 1)$. Straightforward application of triangle inequality shows that the latter conditions hold if $f_0(\Delta_0) \subset B(x_i, s)$ for each i and $s < \frac{2}{2+k}$.

Now we are coming back to the solution of the problem.

Fix a fine triangulation of W so that M becomes a sub-complex of W. We can assume that the diameter of each simplex in τ is less than any given $\varepsilon > 0$. Further, we can assume that all the vertices of τ can be colored into colors $(0, \dots, m+1)$ in such a way that the vertices of each simplex get different colors; the latter can be acheaved by passing to the barycentric subdivision of τ. Denote by τ_i the maximal i-dimensional sub-complex of τ with all the vertices colored by $0, \dots, i$.

Let h be the maximal distance from points in W to M. For each vertex v in τ choose a point $v' \in M$ on the distance $\leqslant h$. Note that if v and w are the vertices of one simplex, then

$$|v' - w'|_M < 2\cdot h + \varepsilon.$$

Assume $\frac{2}{m+3} > h$. Fix a positive value $\varepsilon < \frac{2}{m+3} - h$ and use it in the construction of the triangulation τ above. Applying the iterated cone construction for each simplex of τ we get an extension of the map $v \mapsto v'$ defined on τ_0 to $\tau_1, \tau_2, \dots \tau_{m+1}$. According to the estimates above the cone constructions are defined at each of the needed $m+1$ iterations.

This way we get to a retraction $W \to M$. It follows that fundamental class of M vanish in the homology ring of M, a contradiction. $\square$

This problem is a stripped version of the bound on filling radius given by Mikhael Gromov in [86].

Almost constant function. Given a positive integer m, denote by δ_m the expected value of $|x_1|$ for the random unit vector $\boldsymbol{x} = (x_1, \ldots, x_m) \in \mathbb{R}^m$ with respect to the uniform distribution.

Observe that $\delta_m \to 0$ as $m \to \infty$. Indeed, from symmetry and Bunyakovsky inequality we get

$$\tfrac{1}{m} = \tfrac{1}{m}\cdot\mathrm{E}(|\boldsymbol{x}|^2) = \mathrm{E}(x_1^2) \geqslant \mathrm{E}(|x_1|)^2 = \delta_m^2.$$

Since f is 1-Lipschitz,

$$\mathrm{E}(|df(w)|) \leqslant \delta_m$$

for a random vector w in $\mathrm{U}M$.

Note that

$$\begin{aligned}|f\circ\gamma(1) - f\circ\gamma(0)| &= \left|\int_0^1 df(\gamma'(t))\cdot dt\right| \leqslant \\ &\leqslant \int_0^1 |df(\gamma'(t))|\cdot dt.\end{aligned}$$

Assume $\gamma'(0)$ takes random value in $\mathrm{U}M$. By Liouville's theorem on phase volume, the same holds for $\gamma'(t)$ for any fixed t. Therefore

$$\mathrm{E}(|f\circ\gamma(1) - f\circ\gamma(0)|) \leqslant \mathrm{E}\left(\int_0^1 |df(\gamma'(t))|\cdot dt\right) \leqslant \delta_m.$$

By Markov's inequality, the probability of the event

$$|f\circ\gamma(1) - f\circ\gamma(0)| > \varepsilon$$

is at most $\frac{\delta_m}{\varepsilon}$. Hence the result follows. $\square$

I learned the problem from Mikhael Gromov. It gives an example in the Riemannian world of the so called *concentration of measure phenomenon* [see 125, 126].

Chapter 5

Metric geometry

In this chapter, we consider metric spaces. All the necessary material could be found in the first three chapters of the textbook [127].

Let us fix few standard notations.

◇ The distance between two points x and y in a metric space X will be denoted as

$$\operatorname{dist}_x(y), \quad |x-y| \quad \text{or} \quad |x-y|_X,$$

the latter notation is used to emphasize that x and y are points in the space X.

◇ A metric space X is called *length-metric space* if for any $\varepsilon > 0$ two points $x, y \in X$ can be connected by curve α such that

$$\operatorname{length}\alpha < |x-y|_X + \varepsilon.$$

In this case the metric on X is called a *length-metric.*

Embedding of a compact

Prove that any compact metric space is isometric to a subset of a compact length-metric spaces.

Semisolution. Let K be a compact metric space. Denote by $B(K,\mathbb{R})$ the space of real-valued bounded functions on K equipped with sup-norm; that is,

$$|f| = \sup\{\, |f(x)| \mid x \in K \,\}.$$

Note that the map $K \to B(K,\mathbb{R})$, defied by $x \mapsto \operatorname{dist}_x$ is a distance preserving embedding. Indeed,cby triangle inequality we have

$$|\operatorname{dist}_x(z) - \operatorname{dist}_y(z)| \leqslant |x-y|_K$$

for any $z \in K$ and the equality holds for $z = x$.

In other words we can (and will) consider K as a subspace of $B(K, \mathbb{R})$.

Denote by W the linear convex hull of the image K in $B(K, \mathbb{R})$; that is, W is the intersection of all closed convex subsets containing K. Clearly W is a complete subspace of $B(K, \mathbb{R})$.

Since K is compact we can choose a finite ε-net K_ε in K. Evidently convex hull W_ε of K_ε is compact and W lies in the ε-neighborhood of W_ε. Therefore, W admits a compact ε-net for any $\varepsilon > 0$. That is, W is totally bounded and complete and therefore compact.

Note that a line segments in W are geodesics for the metric induced by sup-norm. In particular W is a compact length-metric space as required. □

The map $x \mapsto \operatorname{dist}_x$ is called *Kuratowski embedding*, it was constructed in [128], essentially the same map was described by Maurice Fréchet in the same paper he introduced metric spaces [see 129].

Non-contracting map°

A map $f\colon X \to Y$ between metric spaces is called *non-contracting* if

$$|f(x) - f(x')|_Y \geqslant |x - x'|_X$$

for any two points $x, x' \in X$.

📖 *Let K be a compact metric space and*

$$f\colon K \to K$$

be a non-contracting map. Prove that f is an isometry.

Finite-whole extension

A map $f\colon X \to Y$ between metric spaces is called *non-expanding* if

$$|f(x) - f(x')|_Y \leqslant |x - x'|_X$$

for any two points $x, x' \in X$.

📖 *Let X and Y be metric spaces, Y is compact, $A \subset X$ and $f\colon A \to Y$ be a non-expanding map. Assume that for any finite set $F \subset X$ there is a non-expanding map $F \to Y$ which agrees with f in $F \cap A$. Show that there is a non-expanding map $X \to Y$ which agrees with f on A.*

Horo-compactification°

Let X be a metric space. Denote by $C(X,\mathbb{R})$ the space of continuous functions $X \to \mathbb{R}$ equipped with the *compact-open topology*; that is, for any compact set $K \subset X$ and open set $U \subset \mathbb{R}$ the set of all continuous functions $f\colon X \to \mathbb{R}$ such that $f(K) \subset U$ is declared to be open.

Fix a point $x_0 \in X$. Given a point $z \in X$, let $f_z \in C(X,\mathbb{R})$ be the function defined as

$$f_z(x) = \operatorname{dist}_z(x) - \operatorname{dist}_z(x_0).$$

Let $F_X\colon X \to C(X,\mathbb{R})$ be the map defined as $F_X\colon z \mapsto f_z$.

Denote by $\bar{X}$ the closure of $F_X(X)$ in $C(X,\mathbb{R})$; note that $\bar{X}$ is compact. That is, if F_X is an embedding, then $\bar{X}$ is a compactification of X, which is called *horo-compactification*. In this case, the complement $\partial_\infty X = \bar{X}\backslash F_X(X)$ is called *horo-absolute* of X.

The construction above is due to Mikhael Gromov [see 130].

Construct a proper metric space X such that

$$F_X\colon X \to C(X,\mathbb{R})$$

is not an embedding. Show that there are no such examples among proper length-metric spaces.

A ball and a sphere

Construct a sequence of Riemannian metrics on $\mathbb{S}^3$ which converges in the sense of Gromov–Hausdorff to the unit ball in $\mathbb{R}^3$.

Macroscopic dimension°

Let X be a locally compact metric space, m is an integer and $a > 0$.

Following Mikhael Gromov [see 131], we say that the *macroscopic dimension* of X at the scale a is m if m is the least integer such that there is a continuous map f from X to an m-dimensional simplicial complex K such that

$$\operatorname{diam}[f^{-1}\{k\}] < a$$

for any $k \in K$.

Equivalently, the macroscopic dimension of X on scale a can be defined as the least integer m such that X admits an open covering with diameter of each set less than a and such that each point in X is covered by at most $m+1$ sets in the cover.

Let M be a simply connected Riemannian manifold with the following property: any closed curve is null-homotopic in its own 1-neighborhood. Prove that the macroscopic dimension of M on the scale 100 *is at most* 1*.*

No Lipschitz embedding*

Construct a length-metric d on $\mathbb{R}^3$, such that the subspace $(\mathbb{R}^3, d)$ does not admit a locally Lipschitz embedding into the 3-dimensional Euclidean space.

Sub-Riemannian sphere+

Let us define sub-Riemannian metric.

Fix a Riemannian manifold (M, g). Assume that in the tangent bundle $\mathrm{T}M$ a choice of sub-bundle H is given.

Let us call the sub-bundle H *horizontal distribution*. The tangent vectors which lie in H will be called *horizontal*. A piecewise smooth curve will be called *horizontal* if all its tangent vectors are horizontal.

The sub-Riemannian distance between points x and y is defined as infimum of lengths of horizontal curves connecting x to y.

Alternatively, the distance can be defined as a limit of Riemannian distances for the metrics

$$g_\lambda(X,Y) = g(X^H, Y^H) + \lambda{\cdot}g(X^V, Y^V)$$

as $\lambda \to \infty$, where X^H denotes the horizontal part of X; that is, the orthogonal projection of X to H and X^V denotes the vertical part of X; so, $X^V + X^H = X$.

In addition we need to add the a condition to ensures the following properties

- ◇ The sub-Riemannian metric induce the original topology on the manifold. In particular, if M is connected, then the distance cannot take infinite values.
- ◇ Any curve in M can be arbitrary well approximated by a horizontal curve with the same endpoints.

The most common condition of this type is so called *complete non-integrability*; it means that for any $x \in M$, one can choose a basis in its tangent space T_xM from the vectors of the following type

$$A(x),\ \ [A,B](x), [A,[B,C]](x), [A,[B,[C,D]]](x), \dots$$

where $[*,*]$ denotes the Lie bracket and all the vector fields $A, B, C, D, \dots$ are horizontal.

🕮 *Prove that any sub-Riemannian metric on the $\mathbb{S}^m$ is isometric to the intrinsic metric of a hypersurface in $\mathbb{R}^{m+1}$.*

It will be hard to solve the problem without knowing proof of Nash–Kuiper theorem on length preserving C^1-embeddings. The original papers of John Nash and Nicolaas Kuiper [see 132, 133] are very readable.

Length-preserving map$^+$

A continuous map $f\colon X \to Y$ between metric spaces is called *length-preserving* if it preserves the length of curves; that is, for any curve α in X we have

$$\operatorname{length}(f \circ \alpha) = \operatorname{length} \alpha.$$

🕮 *Show that there is no length-preserving map $\mathbb{R}^2 \to \mathbb{R}$.*

The expected solution use Rademacher's theorem on differentiability of Lipschitz functions [see 134].

Fixed segment

🕮 *Let $\rho(x, y) = \|x - y\|$ be a metric on $\mathbb{R}^m$ induced by a norm $\|{*}\|$.*

Assume that $f\colon (\mathbb{R}^m, \rho) \to (\mathbb{R}^m, \rho)$ is an isometry which fixes two distinct points a and b. Show that f fixes the line segment between a and b.

Evidently f maps the line segment to a minimizing geodesic connecting a to b in $(\mathbb{R}^m, \rho)$, but in general there might be many minimizing geodesics connecting a to b in $(\mathbb{R}^m, \rho)$.

Pogorelov's construction$^\circ$

🕮 *Let μ be a regular centrally symmetric finite measure on $\mathbb{S}^2$ which is positive on every open set. Given two points $x, y \in \mathbb{S}^2$, set*

$$\rho(x, y) = \mu[B(x, \tfrac{\pi}{2}) \backslash B(y, \tfrac{\pi}{2})].$$

Show that ρ is a length-metric on $\mathbb{S}^2$ and moreover, the images of geodesics in this metric are arcs of great circles in $\mathbb{S}^2$.

Straight geodesics

🕮 *Let ρ be a length-metric on $\mathbb{R}^m$, which is bi-Lipschitz equivalent to the canonical metric. Assume that every geodesic γ in $(\mathbb{R}^d,\rho)$ is linear (that is, $\gamma(t)=v+w\cdot t$ for some $v,w\in\mathbb{R}^m$). Show that ρ is induced by a norm on $\mathbb{R}^m$.*

Hyperbolic space

Recall that a map $f\colon X\to Y$ between metric spaces is called bi-Lipschitz if there if a constant $\varepsilon>0$ such that

$$\varepsilon\cdot|x-y|_X\leqslant|f(x)-f(y)|_Y\leqslant\tfrac{1}{\varepsilon}\cdot|x-y|_X.$$

for any $x,y\in X$.

🕮 *Construct a bi-Lipschitz map from the hyperbolic* 3*-space to the product of two hyperbolic planes.*

A homeomorphism near quasi-isometry^{+}

A map $f\colon X\to Y$ between metric spaces is called a *quasi-isometry* if there is a real constant $C>1$ such that

$$\tfrac{1}{C}\cdot|x-x'|_X-C\leqslant|f(x)-f(x')|_Y\leqslant C\cdot|x-x'|_X+C$$

for any $x,x'\in X$ and $f(X)$ is a C*-net* in Y; that is, for any $y\in Y$ there is $x\in X$ such that $|f(x)-y|_Y\leqslant C$.

Note that a quasi-isometry is not assumed to be continuous, for example any map between compact metric spaces is a quasi-isometry.

🕮 *Let $f\colon\mathbb{R}^m\to\mathbb{R}^m$ be a quasi-isometry. Show that there is a (bi-Lipschitz) homeomorphism $h\colon\mathbb{R}^m\to\mathbb{R}^m$ on a bounded distance from f; that is,*

$$|f(x)-h(x)|\leqslant C$$

for any $x\in\mathbb{R}^m$ and a real constant C.

The expected solution requires a corollary of the theorem of Laurence Siebenmann [135]. It states that if $V_1,V_2\subset\mathbb{R}^m$ are open and the two embedding $f_1\colon V_1\to\mathbb{R}^m$ and $f_2\colon V_2\to\mathbb{R}^m$ are sufficiently close to each other on the overlap $U=V_1\cap V_2$, then there is an embedding f defined on an open set W' which is slightly smaller than $W=V_1\cup V_2$ and such that f is sufficiently close to each f_1 and f_2 at the points where they are defined.

The bi-Lipschitz version requires an analogous statement in the category of bi-Lipschitz embeddings; it was proved by Dennis Sullivan [see 136].

A family of sets with no section°

🕮 *Construct a family of closed sets $C_t \subset \mathbb{S}^1$, $t \in [0,1]$ which is continuous in the Hausdorff topology, but does not admit a* section. *That is, there is no path $c\colon [0,1] \to \mathbb{S}^1$ such that $c(t) \in C_t$ for any t.*

Spaces with isometric balls

🕮 *Construct a pair of locally compact length-metric spaces X and Y which are not isometric, but for some fixed points $x_0 \in X$, $y_0 \in Y$ and any radius R the ball $B(x_0, R)_X$ is isometric to the ball $B(y_0, R)_Y$.*

Semisolutions

Non-contracting map. Given any pair of point $x_0, y_0 \in K$, consider two sequences $x_0, x_1, \dots$ and $y_0, y_1, \dots$ such that and $x_{n+1} = f(x_n)$ and $y_{n+1} = f(y_n)$ for each n.

Since K is compact, we can choose an increasing sequence of integers n_k such that both sequences $(x_{n_i})_{i=1}^{\infty}$ and $(y_{n_i})_{i=1}^{\infty}$ converge. In particular, both of these sequences converge in itself; that is,

$$|x_{n_i} - x_{n_j}|_K, |y_{n_i} - y_{n_j}|_K \to 0 \quad \text{as} \quad \min\{i, j\} \to \infty.$$

Since f is non-contracting, we get

$$|x_0 - x_{|n_i - n_j|}| \leqslant |x_{n_i} - x_{n_j}|.$$

It follows that there is a sequence $m_i \to \infty$ such that

$$(*) \qquad x_{m_i} \to x_0 \quad \text{and} \quad y_{m_i} \to y_0 \quad \text{as} \quad i \to \infty.$$

Set

$$\ell_n = |x_n - y_n|_K.$$

Since f is non-contracting, the sequence (ℓ_n) is non-decreasing.

By $(*)$, $\ell_{m_i} \to \ell_0$ as $m_i \to \infty$. It follows that (ℓ_n) is a constant sequence.

In particular

$$|x_0 - y_0|_K = \ell_0 = \ell_1 = |f(x_0) - f(y_0)|_K$$

for any pair of points (x_0, y_0) in K. That is, f is distance preserving, in particular injective.

From $(*)$, we also get that $f(K)$ is everywhere dense. Since K is compact $f\colon K \to K$ is surjective. Hence the result follows. $\square$

This is a basic lemma in the introduction to Gromov–Hausdorff distance [see 7.3.30 in 127]. I learned this proof from Travis Morrison, a students in my MASS class at Penn State, Fall 2011.

As an easy corollary one can get that any surjective non-expanding map maps from compact metric space to it self is an isometry. The following problem due to Aleksander Całka [137]; it is closely related but more involved.

Show that any local isometry from a connected compact metric space to it self is a homeomorphism.

Finite-whole extension. Given a finite set $F \subset X$, denote by $\mathfrak{S}_F$ the set of all non-expanding map maps $h\colon F \to Y$ which agree with f on $F \cap A$. For $x \in F$, consider the set

$$K(F,x) = \{\, h(x) \in Y \mid h \in \mathfrak{S}_F \,\}.$$

By assumption

$$K(F,x) \neq \varnothing \tag{$*$}$$

for any finite set $F \subset X$ and $x \in F$. Further, note that $K(F,x)$ is closed and

$$K(F',x) \supset K(F,x) \tag{$**$}$$

for any other finite set F' such that $x \in F' \subset F$.

Without loss of generality we can assume that A is a maximal set; that is, f can not be extended to a bigger set in such a way that it satisfies the assumptions of the problem. (It follows that A is closed subset of X, but we will not use it.)

Arguing by contradiction, assume $A \neq X$; fix $x \in X \backslash A$. Given $y \in Y$ there is a finite set $F \ni x$ such that $y \notin K(F,x)$. Or equivalently the intersection of all $K(F,x)$ for all finite sets F including x is empty.

By finite intersection property, we can choose a finite collection of finite sets $F_1, \dots F_n$ containing x such that

$$K(F_1,x) \cap \dots \cap K(F_n,x) = \varnothing. \tag{${}^{*}_{**}$}$$

Since the union $F = F_1 \cup \dots \cup F_n$ is finite, $(*)$ and $(**)$ imply

$$K(F_1,x) \cap \dots \cap K(F_n,x) \supset K(F,x) \neq \varnothing,$$

which contradicts $({}^{*}_{**})$. $\square$

This observation was used by Stephan Stadler and me [in 138].

Horo-compactification. For the first part of the problem, take X to be the set of non-negative integers with the metric ρ defined as

$$\rho(m,n) = m + n$$

for $m \neq n$.

The second part is proved by contradiction. Assume X is proper length space and F_X is not an embedding. That is, there is a sequence of points $z_1, z_2, \dots$ and a point z_∞, such that $f_{z_n} \to f_{z_\infty}$ in $C(X,\mathbb{R})$ as $n \to \infty$, while $|z_n - z_\infty|_X > \varepsilon$ for some fixed $\varepsilon > 0$ and all n.

Note that any pair of points $x, y \in X$ can be connected by a minimizing geodesic $[xy]$. Choose $\bar z_n$ on a geodesic $[z_\infty z_n]$ such that $|z_\infty - \bar z_n| = \varepsilon$. Note that

$$f_{z_n}(z_\infty) - f_{z_n}(\bar z_n) = \varepsilon$$

and

$$f_{z_\infty}(z_\infty) - f_{z_n}(\bar z_n) = -\varepsilon$$

for any n.

Since X is proper, we can pass to a subsequence of z_n so that the sequence $\bar z_n$ converges; denote its limit by $\bar z_\infty$. From the identities above, it follows that

$$f_{z_n}(\bar z_\infty) \not\to f_{z_\infty}(\bar z_\infty) \quad \text{or} \quad f_{z_n}(z_\infty) \not\to f_{z_\infty}(z_\infty),$$

a contradiction. □

I learned this problem from Linus Kramer and Alexander Lytchak; the example was also mentioned in the lectures of Anders Karlsson and attributed to Uri Bader [see 2.3 in 139].

A ball near a sphere. Make fine burrows in the standard 3-ball which do not change its topology, but at the same time come sufficiently close to any point in the ball.

Consider the doubling of obtained ball along its boundary. The obtained space is homeomorphic to $\mathbb{S}^3$. Note that the burrows can be made so that the obtained space is sufficiently close to the original ball in the Gromov–Hausdorff metric.

It remains to smooth the obtained space slightly to get a genuine Riemannian metric with needed property. □

This construction is a stripped version of the theorem of Steven Ferry and Boris Okunin [see 140]. The theorem states that Riemannian metrics on a smooth closed manifold M with $\dim M \geqslant 3$ can approximate the given compact length-metric space X if and only if there is a continuous map $M \to X$ which is surjective on the fundamental groups.

The two-dimensional case is quite different. There is no sequence of Riemannian metrics on $\mathbb{S}^2$ which converge to the unit disc in the sense of Gromov–Hausdorff. In fact, if X is a limit of $(\mathbb{S}^2, g_n)$, then any point $x_0 \in X$ either admits a neighborhood homeomorphic to $\mathbb{R}^2$ or it is a cut point; that is, $X\backslash\{x_0\}$ is disconnected [see 3.32 in 59].

Macroscopic dimension. The following claim resembles Besikovitch inequality; it is a key to the proof.

$(*)$ *Let a be a positive real number. Assume that a closed curve γ in a metric space X can be sudivided into 4 arcs α, β, α', and β' in such a way that*

- $\diamond$ $|x - x'| > a$ *for any* $x \in \alpha$ *and* $x' \in \alpha'$ *and*
- $\diamond$ $|y - y'| > a$ *for any* $y \in \beta$ *and* $y' \in \beta'$.

Then γ is not contractable in its $\frac{a}{2}$-neighborhood.

To prove $(*)$, consider two functions of X defined as

$$w_1(x) = \max\{\, a, \mathrm{dist}_\alpha(x)\,\}$$
$$w_2(x) = \max\{\, a, \mathrm{dist}_\beta(x)\,\}$$

and the map $\boldsymbol{w}\colon X \to [0,a] \times [0,a]$, defined as

$$\boldsymbol{w}\colon x \mapsto (w_1(x), w_2(x)).$$

Note that

$$\begin{aligned} \boldsymbol{w}(\alpha) &= 0 \times [0,a], & \boldsymbol{w}(\beta) &= [0,a] \times 0,\\ \boldsymbol{w}(\alpha') &= a \times [0,a], & \boldsymbol{w}(\beta') &= [0,a] \times a, \end{aligned}$$

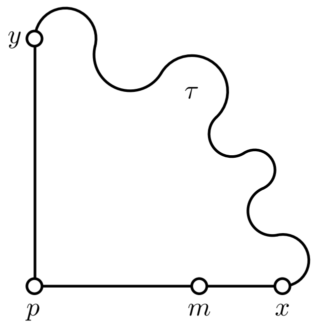
Therefore, the composition $\boldsymbol{w} \circ \gamma$ is a degree 1 map

$$\mathbb{S}^1 \to \partial([0,a] \times [0,a]).$$

It follows that if $h\colon \mathbb{D} \to X$ shrinks γ then there is a point $z \in \mathbb{D}$ such that $\boldsymbol{w} \circ h(z) = (\frac{a}{2}, \frac{a}{2})$. Therefore $h(z)$ lies on the distance at least $\frac{a}{2}$ from α, β, α', β' and therefore from γ. Hence the claim $(*)$ follows.

Fix a point $p \in M$. Let us cover M by the connected components of the inverse images $\mathrm{dist}_p^{-1}((n-1, n+1))$ for all integers n. Clearly any point in M is covered by at most two such components. It remains to show that each of these components has diameter less than 100.

Assume the contrary; let x and y be two points in one connected component and $|x-y|_M \geqslant 100$. Connect x to y by a curve τ in the component. Consider the closed curve σ formed by two geodesics $[px]$, $[py]$ and τ.

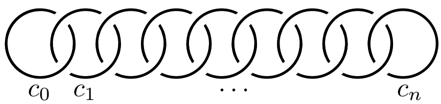


Note that $|p-x|>40$. Therefore there is a point m on $[px]$ such that $|m-x|=20$.

By triangle inequality, the subsdivision of σ into the arcs $[pm]$, $[mx]$, τ and $[yp]$ satisfy the assumption of the claim $(*)$ for $a=10$. Hence the statement follows. □

The problem was discussed in a talk by Nikita Zinoviev around 2004.

No Lipschitz embedding. Consider a chain of circles $c_0,\dots,c_n$ in $\mathbb{R}^3$; that is, c_i and c_{i-1} are linked for each i.



Assume that $\mathbb{R}^3$ is equipped with a length-metric ρ, such that the total length of the circles is ℓ and U is an open bounded set containing all the circles c_i. Note that for any L-Lipschitz embedding $f\colon (U,\rho)\to\mathbb{R}^3$ the distance from $f(c_0)$ to $f(c_n)$ is less than $L\cdot\ell$.

Let us show that the ρ-distance from c_0 to c_n might be much larger than ℓ. Fix a line segment $[ab]$ in $\mathbb{R}^3$. Modify the length-metric on $\mathbb{R}^3$ in a small neighborhood of $[ab]$ so that there is a chain (c_i) of circles as above, which goes from a to b such that (1) the total length, say ℓ, of (c_i) is arbitrary small, but (2) the obtained metric ρ is arbitrary close to the canonical, say

$$\big|\rho(x,y)-|x-y|\big|<\varepsilon$$

for any two points $x,y\in\mathbb{R}^3$ and fixed in advanced small value $\varepsilon>0$. The construction of ρ is done by shrinking the length of each circle and expanding the length in the normal directions to the circles in their small neighborhood. The latter is made in order to make impossible to use the circles c_i as a shortcut; that is, one spends more time to go from one circle to an other than saves on going along the circle.

Set $a_n=(0,\frac1n,0)$ and $b_n=(1,\frac1n,0)$. Note that the line segments $[a_nb_n]$ are disjoint and converging to $[a_\infty b_\infty]$ where $a_\infty=(0,0,0)$ and $b_\infty=(1,0,0)$.

Apply the above construction in non-overlapping convex neighborhoods of $[a_n b_n]$ and for a sequences ε_n and ℓ_n which converge to zero very fast.

The obtained length-metric ρ is still close to the canonical metric on $\mathbb{R}^3$, but it does not admit a locally Lipschitz homeomorphism to $\mathbb{R}^3$. Indeed, assume such homeomorphism h exists. Fix a bounded open set U containing $[a_\infty b_\infty]$; note that the restriction $h|_U$ is L-Lipschitz for some L. From the above construction, we get

$$\begin{aligned}|h(a_\infty) - f(b_\infty)| \leqslant |h(a_n) - f(b_n)| + &\\ + |h(a_\infty) - f(a_n)| + |h(b_n) - f(b_\infty)| &\leqslant \\ \leqslant L\cdot\ell_n + \tfrac{2}{n} + 100\cdot\varepsilon_n&\end{aligned}$$

for any positive integer n. The right hand side converges to 0 as $n \to \infty$. Therefore

$$h(a_\infty) = f(b_\infty),$$

a contradiction. $\square$

The problem is due Dmitri Burago, Sergei Ivanov and David Shoenthal [see 141].

It is expected that any metric on $\mathbb{R}^2$ admits local Lipschitz embeddings into the Euclidean plane. Also, it seems feasible that any metric on $\mathbb{R}^3$ admits a locally Lipschitz embedding into $\mathbb{R}^4$.

Note that any metric on $\mathbb{R}^3$ admits a proper locally Lipschitz map to $\mathbb{R}^3$ of degree 1. Moreover one can make this map injective on any finite set of points. It is instructive to visualize this map for the metric as in the solution.

Sub-Riemannian sphere. By the definition, if d is a sub-Riemannian metric on $\mathbb{S}^m$, then there is a non-decreasing sequence of Riemannian metric tensors $g_0 < g_1 < \dots$ such that their induced metrics $d_1 < d_2 < \dots$ converge to d. The metric g_0 can be assumed to be a metric on round sphere, so it is induced by an embedding $h_0\colon \mathbb{S}^m \to \mathbb{R}^{m+1}$.

Applying the construction as in Nash–Kuiper theorem, one can produce a sequence of smooth embeddings $h_n\colon \mathbb{S}^m \to \mathbb{R}^{m+1}$ with the induced metrics g'_n such that $|g'_n - g_n| \to 0$. In particular, if we denote by d'_n the metric corresponding to g_n, then $d'_n \to d$ an $n \to \infty$.

From the same construction it follows that if one choose $\varepsilon_n > 0$, depending on h_n, then we can assume that

$$|h_{n+1}(x) - h_n(x)| < \varepsilon_n$$

for any $x \in \mathbb{S}^m$.

Let us introduce two conditions on the values ε_n, called *weak* and *strong*.

The weak condition states that $\varepsilon_n < \frac{1}{2}\cdot\varepsilon_{n-1}$ for any n. This ensures that the sequence of maps h_n converges pointwise; denote its limit by h_∞.

Denote by $\bar{d}$ the length-metric induced by h_∞. Note that $\bar{d} \leqslant d$. The strong condition on ε_n will ensure that actually $\bar{d} = d$.

Fix n and assume that h_n and therefore ε_{n-1} are constructed already. Set $\Sigma = h_n(\mathbb{S}^m)$ and let Σ_r be the tubular r-neighborhood of Σ. Equip Σ and Σ_r with the induced length-metrics. Since Σ is a smooth hypersurface, we can choose $r_n \in (0, \varepsilon_{n-1}]$ so that the inclusion $\Sigma \hookrightarrow \Sigma_{r_n}$ preserves the distance up to the error $\frac{1}{2^n}$. Then the strong condition says that $\varepsilon_n < \frac{1}{2}\cdot r_n$, which is evidently stronger than the weak condition $\varepsilon_n < \frac{1}{2}\cdot\varepsilon_{n-1}$ above.

Note that if the sequence h_n is constructed with the described choice of ε_n, then $|h_\infty(x) - h_n(x)| < r_n$ for any $x \in \mathbb{S}^m$. Therefore

$$\bar{d}(x,y) + 2\cdot r_n + \tfrac{1}{2^n} \geqslant d_n'(x,y)$$

for any n and $x, y \in \mathbb{S}^m$; hence $\bar{d} \geqslant d$ as required. $\square$

The problem appeared on this list first rediscovered by Enrico Le Donne [see 142]. Similar construction described in the lecture notes by Allan Yashinski and me [see 143] which is aimed for undergraduate students. Yet the results in [144] are closely relevant.

The construction in the Nash–Kuiper embedding theorem can be used to prove some seemingly irrelevant statements. Here is one example based on the observation that Weyl curvature tensor is vanishing on hypersurfaces in the Euclidean space.

- ◇ Let M be a Riemannian manifold diffeomorphic to the n-sphere. Show that there is a Riemannian manifold M' arbitrary close to M in Lipschitz metric and vanishing Weyl curvature tensor.

Length-preserving map. Assume contrary; let $f\colon \mathbb{R}^2 \to \mathbb{R}$ be a length-preserving map.

Note that f is Lipschitz. Therefore by Rademacher's theorem [see 134], f is differentiable almost everywhere.

Fix a unit vector u. Given $x \in \mathbb{R}^2$, consider the path $\alpha_x(t) = x + t\cdot u$ defined for $t \in [0,1]$. Note that for almost all x, the equality

$$\alpha_x'(t) = (d_{\alpha_x(t)} f)(u)$$

holds for almost all t. It follows that

$$\operatorname{length}(f \circ \alpha_x) = \int_0^1 |(d_{\alpha_x(t)} f)(u)|\cdot dt$$

for almost all x.

Therefore $|d_x f(v)| = |v|$ for almost all $x, v \in \mathbb{R}^2$. In particular there is $x \in \mathbb{R}^2$ such that the differential $d_x f$ is defined and has rank 2, a contradiction. ☐

The idea above can be also used to solve the following problem.

🕮 *Assume ρ is a metric on $\mathbb{R}^2$ which is induced by a norm. Show that $(\mathbb{R}^2, \rho)$ admits a length-preserving map to $\mathbb{R}^3$ if and only if $(\mathbb{R}^2, \rho)$ is isometric to the Euclidean plane.*

Fixed segment. Note that it is sufficient to show that if

$$f(a) = a \quad \text{and} \quad f(b) = b$$

for some $a, b \in \mathbb{R}^m$, then

$$f(\tfrac{a+b}{2}) = \tfrac{1}{2}\cdot(f(a) + f(b)).$$

Without loss of generality, we can assume that $b + a = 0$.

Set $f_0 = f$. Consider the recursively defined sequence of isometries $f_0, f_1, \ldots$ such that

$$f_{n+1}(x) = -f_n^{-1}(-f_n(x))$$

for any n.

Note that $f_n(a) = a$ and $f_n(b) = b$ for any n and

$$|f_{n+1}(0)| = 2\cdot|f_n(0)|.$$

Therefore if $f(0) \neq 0$, then $|f_n(0)| \to \infty$ as $n \to \infty$. On the other hand, since f_n is isometry and $f(a) = a$, we get $|f_n(0)| \leqslant 2\cdot|a|$, a contradiction. ☐

The idea in the proof is due to Jussi Väisälä's [see 145]. The problem is the main step in the proof of Mazur–Ulam [see 146], which states that any isometry of $(\mathbb{R}^m, \rho)$ to itself is an affine map.

Pogorelov's construction. Positivity and symmetry of ρ is evident.

The triangle inequality follows since

$$(*) \qquad [B(x,\tfrac{\pi}{2})\backslash B(y,\tfrac{\pi}{2})] \cup [B(y,\tfrac{\pi}{2})\backslash B(z,\tfrac{\pi}{2})] \supseteq B(x,\tfrac{\pi}{2})\backslash B(z,\tfrac{\pi}{2})$$

and $B(x,\frac{\pi}{2})\backslash B(y,\frac{\pi}{2})$ does not overlap $B(y,\frac{\pi}{2})\backslash B(z,\frac{\pi}{2})$.

Note that we get equality in $(*)$ if and only if y lies on the great circle arc from x to z. Therefore the second statement follows. ☐

This construction was given by Aleksei Pogorelov [see 147]. It is closely related to the construction given by David Hilbert in [see 148] which was the motivating example of his 4th problem.

Straight geodesics. From the uniqueness of straight segment between given points in $\mathbb{R}^m$, it follows that any straight line in $\mathbb{R}^m$ is a geodesic in $(\mathbb{R}^m,\rho)$.

Set

$$\|\boldsymbol{v}\|_{\boldsymbol{x}} = \rho(\boldsymbol{x},(\boldsymbol{x}+\boldsymbol{v})).$$

Note that

$$\|\lambda\cdot\boldsymbol{v}\|_{\boldsymbol{x}} = |\lambda|\cdot\|\boldsymbol{v}\|_{\boldsymbol{x}}$$

for any $\boldsymbol{x},\boldsymbol{v}\in\mathbb{R}^m$ and $\lambda\in\mathbb{R}$.

Since ρ is bi-Lipschitz to $|*-*|$, applying triangle inequality twice for the points $\boldsymbol{x}$, $\boldsymbol{x}+\lambda\cdot\boldsymbol{v}$, $\boldsymbol{x}'$ and $\boldsymbol{x}'+\lambda\cdot\boldsymbol{v}$, we get

$$\|\lambda\cdot\boldsymbol{v}\|_{\boldsymbol{x}} - \|\lambda\cdot\boldsymbol{v}\|_{\boldsymbol{x}'} \leqslant C\cdot|\boldsymbol{x}-\boldsymbol{x}'|$$

for any $\boldsymbol{x},\boldsymbol{x}',\boldsymbol{v}\in\mathbb{R}^m$, $\lambda\in\mathbb{R}$ and a fixed real constant C.

Passing to the limit as $\lambda\to\infty$, we get $\|\boldsymbol{v}\|_{\boldsymbol{x}}$ does not depend on $\boldsymbol{x}$; hence the result follows. $\square$

The idea is due to Thomas Foertsch and Viktor Schroeder [see 149]. A more general statement was proved by Petra Hitzelberger and Alexander Lytchak in [150]. Namely they show that if any pair of points in a geodesic metric space X can be separated by an affine function, then X is isometric to a convex subset in a normed vector space. (A function $f\colon X\to\mathbb{R}$ is called affine if the composition $f\circ\gamma$ is affine for any geodesic γ in X.)

Hyperbolic space. The hyperbolic plane $\mathbb{H}^2$ can be viewed as $(\mathbb{R}^2,g)$, where

$$g(x,y)=\begin{pmatrix}1&0\\0&e^x\end{pmatrix}.$$

The same way, the hyperbolic space $\mathbb{H}^3$ can be viewed as $(\mathbb{R}^3,h)$, where

$$h(x,y,z)=\begin{pmatrix}1&0&0\\0&e^x&0\\0&0&e^x\end{pmatrix}.$$

In the described coordinates, consider the projections $\mathbb{H}^3\to\mathbb{H}^2$ defined as $\varphi\colon(x,y,z)\mapsto(x,y)$ and $\psi\colon(x,y,z)\mapsto(x,z)$. Note that

$$\begin{aligned}|\varphi(p)-\varphi(q)|_{\mathbb{H}^2},\quad |\psi(p)-\psi(q)|_{\mathbb{H}^2}\leqslant |p-q|_{\mathbb{H}^3}\leqslant&\\ \leqslant |\varphi(p)-\varphi(q)|_{\mathbb{H}^2}+|\psi(p)-\psi(q)|_{\mathbb{H}^2}&\end{aligned}$$

for any two points $p,q\in\mathbb{H}^3$. In particular, the map $\mathbb{H}^3\to\mathbb{H}^2\times\mathbb{H}^2$ defined as $p\mapsto(\varphi(p),\psi(p))$ is $2^{\mp1}$-bi-Lipschitz. $\square$

We used that horo-sphere in the hyperbolic space is isometric to the Euclidean plane. This observation appears already in the book of Nikolai Lobachevsky [see 34 in 151].

A homeomorphism near quasi-isometry. Fix two constants $M\geqslant 1$ and $A\geqslant 0$. A map $f\colon X\to Y$ between metric spaces X and Y such that for any $x,y\in X$, we have

$$\tfrac{1}{M}\cdot|x-y|-A\leqslant|f(x)-f(y)|\leqslant M\cdot|x-y|+A$$

and any point in Y lies on the distance at most A from a point in the image $f(X)$ will be called (M,A)-quasi-isometry.

Note that $(M,0)$-quasi-isometry is a $[\tfrac{1}{M},M]$-bi-Lipschitz map. Moreover, if $f_n\colon\mathbb{R}^m\to\mathbb{R}^m$ is a $(M,\tfrac{1}{n})$-quasi-isometry for each n, then any partial limit of f_n as $n\to\infty$ is a $[\tfrac{1}{M},M]$-bi-Lipschitz map.

It follows that given $M\geqslant 1$ and $\varepsilon>0$ there is $\delta>0$ such that for any (M,δ)-quasi-isometry $f\colon\mathbb{R}^m\to\mathbb{R}^m$ and any $p\in\mathbb{R}^m$ there is an $[\tfrac{1}{M},M]$-bi-Lipschitz map $h\colon B(p,1)\to\mathbb{R}^m$ such that

$$|f(x)-h(x)|<\varepsilon$$

for any $x\in B(p,1)$.

Applying rescaling, we can get the following equivalent formulation. Given $M\geqslant 1$, $A\geqslant 0$ and $\varepsilon>0$ there is big enuf $R>0$ such that for any (M,A)-quasi-isometry $f\colon\mathbb{R}^m\to\mathbb{R}^m$ and any $p\in\mathbb{R}^m$ there is a $[\tfrac{1}{M},M]$-bi-Lipschitz map $h\colon B(p,R)\to\mathbb{R}^m$ such that

$$|f(x)-h(x)|<\varepsilon\cdot R$$

for any $x\in B(p,R)$.

Cover $\mathbb{R}^m$ by balls $B(p_n,R)$, construct a $[\tfrac{1}{M},M]$-bi-Lipschitz map $h_n\colon B(p_n,R)\to\mathbb{R}^m$ close to the restrictions $f|_{B(p_n,R)}$ for each n.

The maps h_n are $2\cdot\varepsilon\cdot R$ close to each other on the overlaps of their domains of definition. This makes possible to deform slightly each h_n so that they agree on the overlaps. This can be done by Siebenmann's Theorem [135]. If instead you apply Sullivan's theorem [136], you get a bi-Lipschitz homeomorphism $h\colon\mathbb{R}^m\to\mathbb{R}^m$. $\square$

The problem was suggested by Dmitri Burago.

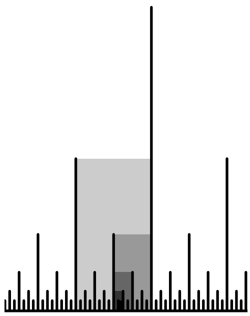
A family of sets with no section. Given $t\in(0,1]$ consider the real interval $\tilde C_t=[\tfrac{1}{t}+t,\tfrac{1}{t}+1]$. Denote by C_t the image of $\tilde C_t$ under the covering map $\pi\colon\mathbb{R}\to\mathbb{S}^1=\mathbb{R}/\mathbb{Z}$.

Set $C_0=\mathbb{S}^1$. Note that Hausdorff distance from C_0 to C_t is $\tfrac{t}{2}$. Therefore $\{C_t\}_{t\in[0,1]}$ is a family of compact subsets in $\mathbb{S}^1$ which is continuous in the sense of Hausdorff.

Assume there is a continuous section $c(t)\in C_t$, for $t\in[0,1]$. Since π is a covering map, we can lift the path c to a path $\tilde c\colon[0,1]\to\mathbb{R}$ such that $\tilde c(t)\in\tilde C_t$ for any t. In particular $\tilde c(t)\to\infty$ as $t\to 0$, a contradiction. $\square$

The problem is suggested by Stephan Stadler. Here is a simpler, closely related problem.

Show that any Hausdorff continuous family of compact sets in $\mathbb{R}$ *admits a continuous section.*



Spaces with isometric balls. The needed examples can be constructed from the upper half-plane by cutting it along a "dyadic comb" shown on the diagram and equipping the obtained space with the intrinsic metric induced from the ℓ_∞-norm on the plane. Few concentric balls in this metric are shown on the diagram.

First let us describe the the comb precisely. Fix an infinite sequence $a_0,a_1,\dots$ of zeros and ones. Given an integer k cut a the upper half-plane along the line segment from $(k,0)$ to $(k,2^{m+1})$ if m is the maximal number such that

$$k\equiv a_0+2\cdot a_1+\dots+2^{m-1}\cdot a_{m-1}\pmod{2^m};$$

If the equality holds for all m, cut the plane along the vertical half-plane from $(k,0)$.

Note that all the obtained spaces, independently from the sequence (a_n), meet the conditions for the point $x_0=(\frac12,0)$.

Note yet that the resulting spaces for two sequences (a_n) and (a'_n) are isometric only in the following two cases

◇ if $a_n=a'_n$ for all large n, or

◇ if $a_n=1-a'_n$ for all large n.

It remains to produce two sequences which do not have these identities for all large n; two random sequences do the job with probability one. $\square$

Chapter 6

Actions and coverings

Bounded orbit

Recall that a metric space is called *proper* if all its bounded closed sets are compact.

Let X be a proper metric space and $\iota\colon X \to X$ is an isometry. Assume that for some $x \in X$, the sequence $x_n = \iota^n(x)$, $n \in \mathbb{Z}$ has a converging subsequence. Prove that x_n is bounded.

Semisolution. Note that we can assume that the orbit $\{x_n\}$ is dense in X; otherwise pass to the closure of the orbit. In particular, we can choose a finite number of positive integer values $n_1, n_2, \dots, n_k$ such that the set of points $\{x_{n_1}, x_{n_2}, \dots, x_{n_k}\}$ is a $\frac{1}{10}$-net for the ball $B(x_0, 10)$; that is, for any $x \in B(x_0, 10)$ there is x_{n_i} such that

$$|x - x_{n_i}| < \tfrac{1}{10}.$$

Assume $x_m \in B(x_0, 1)$ for some m. Then

$$B(x_m, 10) = f^m(B(x_0, 10)) \supset B(x_0, 1).$$

In particular, $\{x_{m+n_1}, x_{m+n_2}, \dots, x_{m+n_k}\}$ is a $\frac{1}{10}$-net for the ball $B(x_0, 1)$ Therefore $x_{m+n_i} \in B(x_0, 1)$ for some $i \in \{1, \dots, k\}$.

Set $N = \max_i\{n_i\}$. Applying the above observation inductively, we get that from any string $x_{i+1}, \dots x_{i+N}$ at least one point lies in $B(x_0, 1)$. In particular, the N balls

$$B(x_1, 10), \dots, B(x_N, 10)$$

cover whole X. Hence the result follows. □

The problem is due to Aleksander Całka's [see 152].

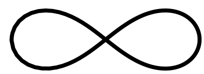
Finite action

Show that for any nontrivial continuous action of a finite group on the unit sphere there is an orbit which does not lie in the interior of a hemisphere.

Covers of figure eight

Given a covering
$$f\colon \tilde X \to X$$
of the length-metric space X, one can consider the induced length-metric on $\tilde X$ defining length of curve α in X as the length of the composition $f\circ\alpha$; the obtained metric space $\tilde X$ is called *metric covering* of X.

Let us define *figure eight* as the length-metric space which is obtained by gluing together all four ends of two unit segments.



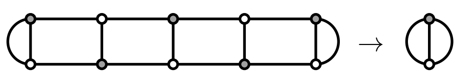
Prove that any compact length-metric space K is a Gromov–Hausdorff limit of a sequence of metric covers
$$(\widetilde\Phi_n, \tilde d/n) \to (\Phi, d/n),$$
where (Φ, d) denotes the figure eight.

Diameter of m-fold cover*

The metric covering is defined in the previous problem.

Let X be a length-metric space and $\tilde X$ be its m-fold metric covering of X. Show that
$$\operatorname{diam}\tilde X \leqslant m\cdot \operatorname{diam} X.$$

From the diagram below you could guess an example of 5-fold cover with diameter of the total space exactly 5 times diameter of the target.

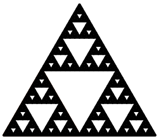


Symmetric square°

Let X be a topological space. Note that $X\times X$ admits a natural $\mathbb{Z}_2$-action generated by the involution $(x,y)\mapsto(y,x)$. The quotient space $X\times X/\mathbb{Z}_2$ is called *symmetric square* of X.

Show that symmetric square of any path connected topological space has commutative the fundamental group.

Sierpiński gasket°



To construct Sierpiński gasket, start with a solid equilateral triangle, subdivide it into four smaller congruent equilateral triangles and remove the interior of the central one. Repeat this procedure recursively for each of the remaining solid triangles.

Find the homeomorphism group of the Sierpiński gasket.

Lattices in a Lie group

Let L and M be two discrete subgroups of a connected Lie group G and h be a left invariant metric on G. Equip the groups L and M with the metrics induced from G. Assume $L\backslash G$ and $M\backslash G$ are compact and

$$\mathrm{vol}(L\backslash(G,h)) = \mathrm{vol}(M\backslash(G,h)).$$

Prove that there is a bi-Lipschitz one-to-one mapping $f\colon L \to M$, not necessarily a homomorphism.

Piecewise Euclidean quotient

Note that the quotient of Euclidean space by a finite subgroup of $\mathrm{SO}(m)$ is a *polyhedral space* as it defined on page 106; on the same page you find the definition of piecewise linear homeomorphism.

Let Γ be a finite subgroup of $\mathrm{SO}(m)$. Denote by P the quotient $\mathbb{R}^m/\Gamma$ equipped with induced polyhedral metric. Assume P admits a piecewise linear homeomorphism to $\mathbb{R}^m$. Show that Γ is generated by rotations around subspaces of codimension 2.

Subgroups of the free group

Show that every finitely generated subgroup of the free group is an intersection of subgroups of finite index.

Lengths of generators of the fundamental group°

Let M be a compact Riemannian manifold and $p \in M$. Show that the fundamental group $\pi_1(M,p)$ is generated by the homotopy classes of loops with length at most $2\cdot \mathrm{diam}\, M$.

Number of generators

🕮 *Let M be a complete connected Riemannian manifold with non-negative sectional curvature. Show that the minimal number of generators of the fundamental group $\pi_1 M$ can be bounded above in terms of the dimension of M.*

Equations in the group°

🕮 *Assume G is a compact connected Lie group and n is a positive integer. Show that given a collection of elements $g_1, g_2 \dots, g_n \in G$ the equation*

$$x{\cdot}g_1{\cdot}x{\cdot}g_2\cdots x{\cdot}g_n = 1$$

has a solution $x \in G$.

Semisolutions

Finite action. Without loss of generality, we may assume that the action is generated by a nontrivial homeomorphism

$$a\colon \mathbb{S}^m \to \mathbb{S}^m$$

with prime order p.

Assume contrary, that is, any a-orbit lies in an open hemisphere. Then

$$h(x) = \sum_{n=1}^{p} a^n{\cdot}x \neq 0$$

for any $x \in \mathbb{S}^m$; here we consider $\mathbb{S}^m$ as the unit sphere in $\mathbb{R}^{m+1}$.

Consider the map $f\colon \mathbb{S}^m \to \mathbb{S}^m$ defined as $f(x) = \frac{h(x)}{|h(x)|}$. Note that

◇ if $a(x) = x$, then $f(x) = x$;

◇ $f(x) = f \circ a(x)$ for any $x \in \mathbb{S}^m$.

Note further that f is homotopic to the identity; in particular

$$(*) \qquad \deg f = 1.$$

The homotopy can be constructed as $(x,t) \mapsto \gamma_x(t)$, where γ_x is the minimizing geodesic path in $\mathbb{S}^m$ from x to $f(x)$. By construction, $|x - f(x)|_{\mathbb{S}^m} < \frac{\pi}{2}$; therefore γ_x is uniquely defined.

Fix $x \in \mathbb{S}^m$ such that $a(x) \neq x$. Note that the group acts without fixed points on the inverse image $W = f^{-1}(V)$ of a small open neighborhood $V \ni x$. Therefore the quotient map $\theta\colon W \to W' = W/\mathbb{Z}_p$ is a p-fold covering. From (6), the restriction $f|_W$ factors thru θ; that is, there is $f'\colon W' \to V$ such that $f|_W = f' \circ \theta$.

Assume $p \neq 2$. Note that f' and θ have well defined degrees and

$$\deg f \equiv \deg \theta \cdot \deg f' \pmod{p}$$

Since θ is a p-fold covering, we have $\deg \theta \equiv 0 \pmod{p}$. Therefore

$$(**) \qquad \deg f \equiv 0 \pmod{p}.$$

Finally observe that $(*)$ contradicts $(**)$.

In the case $p = 2$ the same proof works, but the degrees have to be considered modulo 2. □

Along the same lines one can get a lower bound for the maximal diameter of orbit for any nontrivial actions of finite groups on a Riemannian manifold.

Applying the problem to the conjugate actions, one gets that if a fixed point set of a finite group acting on a sphere has nonempty interior, then the action is trivial. The same holds for any connected manifold. All this was proved by Max Newman [see 153].

The following problem use Newman's theorem; it appears in [154].

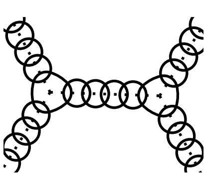
Assume h is a homeomorphism of a connected manifold M such that each h-orbit is finite. Show that h has finite order.

Covers of figure eight. First note that any compact length-metric space K can be approximated by finite metric graph.

Indeed, fix a finite ε-net F in K. For each pair $x, y \in F$ choose a chain of points $x = x_0, x_1 \dots x_n = y$ such that $|x_i - x_{i-1}|_K < \varepsilon$ for each i and

$$|x - y|_K = |x_0 - x_1|_K + \dots + |x_{n-1} - x_n|_K.$$

Denote by F' the union of all these chains with F; Consider the metric graph with F' as the set of vertexes where every pair of vertexes v and w such that $|v - w|_K < \varepsilon$ is connected by an edge of length $|v - w|_K$. Note that the obtained metric graph is ε close to K in the sense of Gromov–Hausdorff.



Further, any finite metric graph is a limit of metric graphs Γ_n such that the length of each edge is a multiple of $\frac{1}{n}$ and degree of each vertex is 3.

It remains to approximate Γ_n by finite coverings of $(\Phi, d/n)$. Guess this part from the picture; it shows the needed covering of figure eight for the doted graph. □

The same idea works if instead of figure eight, we have any compact length-metric space X which admits a map $X \to \Phi$ which is surjective on fundamental groups. Such spaces X can be found among compact hyperbolic manifolds of any dimension $\geqslant 2$. All this due to Vedrin Sahovic [see 155].

A similar idea was used later to show that any group can appear as a fundamental group of underlying space of 3-dimensional hyperbolic orbifold [see 156].

Diameter of *m*-fold cover. Fix points $\tilde{p}, \tilde{q} \in \tilde{M}$. Let $\tilde{\gamma}\colon [0,1] \to \tilde{M}$ be a minimizing geodesic path from $\tilde{p}$ to $\tilde{q}$.

We need to show that

$$\operatorname{length} \tilde{\gamma} \leqslant m \cdot \operatorname{diam} M.$$

Suppose the contrary.

Denote by p, q and γ the projections to M of $\tilde{p}, \tilde{q}$ and $\tilde{\gamma}$. Represent γ as the concatenation of m paths of equal length,

$$\gamma = \gamma_1 * \ldots * \gamma_m,$$

so

$$\operatorname{length} \gamma_i = \tfrac{1}{m} \cdot \operatorname{length} \gamma > \operatorname{diam} M.$$

Let σ_i be a minimizing geodesic in M connecting the endpoints of γ_i. Note that

$$\operatorname{length} \sigma_i \leqslant \operatorname{diam} M < \operatorname{length} \gamma_i.$$

Consider $m+1$ paths $\alpha_0, \ldots, \alpha_m$ defined as the concatenations

$$\alpha_i = \sigma_1 * \ldots * \sigma_i * \gamma_{i+1} * \ldots * \gamma_m.$$

Let $\tilde{\alpha}_0, \ldots, \tilde{\alpha}_m$ be their liftings with $\tilde{q}$ as the endpoint.

The staring points of $\tilde{\alpha}_i$ lies in one of m inverse images of p. Therefore two curves, α_i and α_j for $i < j$, have the same starting point in $\tilde{M}$.

Note that the concatenation

$$\beta = \gamma_1 * \ldots * \gamma_i * \sigma_{i+1} * \ldots * \sigma_j * \gamma_{j+1} * \ldots * \gamma_m.$$

admits a lift $\tilde{\beta}$ which connects $\tilde{p}$ to $\tilde{q}$ in $\tilde{M}$. Clearly $\operatorname{length} \tilde{\beta} < \operatorname{length} \gamma$, a contradiction. □

The question was asked by Alexander Nabutovsky and answered by Sergei Ivanov [see 157].

Symmetric square. Let $\Gamma = \pi_1 X$ and $\Delta = \pi_1((X \times X)/\mathbb{Z}_2)$. Consider the homomorphism $\varphi\colon \Gamma \times \Gamma \to \Delta$ induced by the projection $X \times X \to (X \times X)/\mathbb{Z}_2$.

Note that $\varphi(\alpha,1)=\varphi(1,\alpha)$ for any $\alpha\in\Gamma$ and the restrictions $\varphi|_{\Gamma\times\{1\}}$ and $\varphi|_{\{1\}\times\Gamma}$ are onto.

It remains to note that

$$\varphi(\alpha,1)\varphi(1,\beta)=\varphi(1,\beta)\varphi(\alpha,1)$$

for any α and β in Γ. □

The problem was suggested by Rostislav Matveyev.

Sierpiński gasket. Denote the Sierpiński gasket by $\triangle$.

Let us show that any homeomorphism of $\triangle$ is also its isometry. Therefore the group homeomorphisms is the symmetric group S_3.

Let $\{x,y,z\}$ be a 3-point set in $\triangle$ such that $\triangle\backslash\{x,y,z\}$ has 3 connected components. Note that there is unique choice for the set $\{x,y,z\}$ and it is formed by the midpoints of its big sides.

It follows that any homeomorphism of $\triangle$ permutes the set $\{x,y,z\}$.

A similar argument shows that this permutation uniquely describes the homeomorphism. □

The problem was suggested by Bruce Kleiner. The homeomorphism group of Sierpiński carpet is much more interesting .

Latices in a Lie group. Denote by V_ℓ and W_m the Voronoi domain of for each $\ell\in L$ and $m\in M$ correspondingly; that is,

$$V_\ell=\{\,g\in G\mid |g-\ell|_G\leqslant|g-\ell'|_G \text{ for any } \ell'\in L\,\}$$

$$W_m=\{\,g\in G\mid |g-m|_G\leqslant|g-m'|_G \text{ for any } m'\in M\,\}$$

Note that for any $\ell\in L$ and $m\in M$ we have

$$\begin{aligned}\operatorname{vol}V_\ell&=\operatorname{vol}(L\backslash(G,h))=\\&=\operatorname{vol}(M\backslash(G,h))=\\&=\operatorname{vol}W_m.\end{aligned}\tag{$*$}$$

Consider the bipartite graph Γ with the parts L and M such that $\ell\in L$ is adjacent to $m\in M$ if and only if $V_\ell\cap W_m\neq\varnothing$.

By $(*)$ the graph Γ satisfies the condition in the marriage theorem — any subset in L has at least that many neighbors in M and the other way around [see 158]. Therefore there is a bijection $f\colon L\to M$ such that

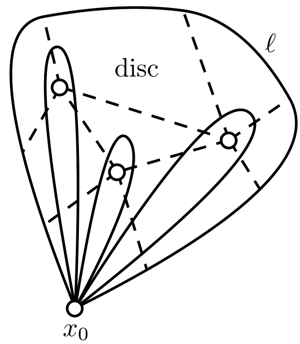
$$V_\ell\cap W_{f(\ell)}\neq\varnothing$$

for any $\ell\in L$.

It remains to observe that f is bi-Lipschitz. □

The problem is due to Dmitri Burago and Bruce Kleiner [see 159]. For a finitely generated group G it is not known if G and $G \times \mathbb{Z}_2$ can fail to be bi-Lipschitz. (The groups are assumed to be equipped with word metric.)

Piecewise Euclidean quotient. Note that the group Γ serves as holonomy group of the quotient space $P = \mathbb{R}^m/\Gamma$ with the induced polyhedral metric. More precisely, one can identify $\mathbb{R}^m$ with the tangent space of a regular point x_0 of P in such a way that for any $\gamma \in \Gamma$ there is a loop ℓ in P which pass only thru regular points and has the holonomy γ.



Fix γ and ℓ as above. Since P is simply connected, we can shrink ℓ by a disc. By general position argument we can assume that the disc only pass thru simplices of codimension 0, 1 and 2 and intersect the simplices of codimension 2 transversely.

In other words, ℓ can be presented as a product of loops such that each loop goes around a single simplex of codimension 2 and comes back. The holonomy for each of these loops is a rotation around a hyperplane. Hence the result follows. $\square$

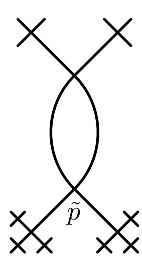
The converse to the problem also holds; it was proved by Christian Lange in [160], his proof based earlier results of Marina Mikhailova [see 161].

Note that the cone over spherical suspension over Poincaré sphere is homeomorphic to $\mathbb{R}^5$ and it is the quotient of $\mathbb{R}^5$ by the binary icosahedral group, which is a subgroup of SO(5) of order 120. Therefore, if one exchanges "piecewise linear homeomorphism" to "homeomorphism" in the formulation, then the answer is different; a complete classification of such actions is given in [160].

Subgroups of free group. The proof exploits that free group is a fundamental group of graph.

Let F be a free group and G be a finitely generated subgroup in F. We need to show that G is an intersection of subgroups of finite index in F. Without loss of generality we can assume that F has finite number generators, denote it by m.

Let W be the wedge sum of m circles, so $\pi_1(W,p) = F$. Equip W with the length-metric such that each circle has unit length.



$\bar{B}(\tilde{p}, 2 + \frac{1}{2})$

Pass to the metric cover $\tilde W$ of W such that $\pi_1(\tilde W,\tilde p)=G$ for a lift $\tilde p$ of p.

Fix sufficiently large integer n and consider doubling of the closed ball $\bar B(\tilde p,n+\tfrac12)$ along its boundary. Let us denote the obtained doubling by Z_n and set $G_n=\pi(Z_n,\tilde p)$.

Note that Z_n is a metric covering of W; it makes possible to consider G_n as a subgroup of F. By construction, Z_n is compact; therefore G_n has finite index in F.

It remains to show that

$$G=\bigcap_{n>k}G_n,$$

where k is the maximal length of word in the generating set of G. □

Originally the problem was solved by Marshall Hall in [158]. The proof presented here is close to the solution of John Stalings in [162]; see also [163].

The same idea can be used to solve many other problems; here are some examples.

- ⋄ *Show that subgroups of free groups are free.*
- ⋄ *Show that two elements of the free groups u and v commute if and only if they are both powers of the some element w.*

Lengths of generators of the fundamental group. Choose a length minimizing loop γ which represents a given element $a\in\pi_1M$.

Fix $\varepsilon>0$. Represent γ as a concatenation

$$\gamma=\gamma_1*\dots*\gamma_n$$

of paths with length $\gamma_i<\varepsilon$ for each i.

Denote by $p=p_0,p_1,\dots,p_n=p$ the endpoints of these arcs. Connect p to p_i by a minimizing geodesic σ_i. Note that γ is homotopic to a product of loops

$$\alpha_i=\sigma_{i-1}*\gamma_i*\sigma_{i-1}$$

and length $\alpha_i<2\cdot\operatorname{diam}M+\varepsilon$ for each i.

Given $\ell>0$, there are only finitely many elements of fundamental group which which can be realized by loops shorter than ℓ of at p. It follows that for right choice of $\varepsilon>0$, any loop σ_i is homotopic to a loop of length at most $2\cdot\operatorname{diam}M$. Hence the result follows. □

The statement is due to Mikhael Gromov [Proposition 3.22 in 59].

Number of generators. Consider the universal Riemannian cover $\tilde M$ of M. Note that $\tilde M$ is non-negatively curved and π_1M acts by isometries on $\tilde M$.

Fix $p \in \tilde{M}$. Given $a \in \pi_1 M$, set

$$|a| = |p - a \cdot p|_{\tilde{M}}.$$

Consider the so called *short basis* in $\pi_1 M$; that is, a sequence of elements $a_1, a_2, \dots \in \pi_1 M$ defined the following way:

(i) Choose $a_1 \in \pi_1 M$ so that $|a_1|$ takes the minimal value.
(ii) Choose $a_2 \in \pi_1 M \backslash \langle a_1 \rangle$ so that $|a_2|$ takes the minimal value.
(iii) Choose $a_3 \in \pi_1 M \backslash \langle a_1, a_2 \rangle$ so that $|a_2|$ takes the minimal value.
(iv) and so on.

Note that the sequence terminates at n-th step if $a_1, \dots, a_n$ generate $\pi_1 M$. By construction, we have

$$|a_j \cdot a_i^{-1}| \geqslant |a_j| \geqslant |a_i|$$

for any $j > i$. Set $p_i = a_i \cdot p$. Note that

$$\begin{aligned} |p_j - p_i|_{\tilde{M}} &= |a_j \cdot a_i^{-1}| \geqslant \\ &\geqslant |a_j| = \\ &= |p_j - p|_{\tilde{M}} \geqslant \\ &\geqslant |a_i| = \\ &= |p_i - p|_{\tilde{M}}. \end{aligned}$$

By Toponogov comparison theorem we get

$$\measuredangle[p\,{}^{p_i}_{p_j}] \geqslant \tfrac{\pi}{3}.$$

That is, the directions from p to all p_i lie on the angle at least $\frac{\pi}{3}$ from each other.

Therefore the number of points p_i can be bounded in terms of the dimension of M. Hence the result follows. $\square$

The *short basis construction* as well as the result above are due to Mikhael Gromov [see 66].

Equations in the group. We will assume that G is equipped with bi-invariant metric. In particular geodesics starting from $1 \in G$ are given by homomorphisms $\mathbb{R} \to G$.

Consider the map $f \colon G \to G$ defined as

$$f(x) = x \cdot g_1 \cdot x \cdot g_2 \cdots x \cdot g_n.$$

We need to show that f is onto. Note that it is sufficient to show that f has non zero degree.

The map f is homotopic to the map $h\colon x\mapsto x^n$. Therefore it is sufficient to show that

$$(*)\qquad \deg h\neq 0$$

Note that the claim $(*)$ follows from $(**)$.

$(**)$ *For any $x\in G$ the differential*

$$d_xh\colon \mathrm{T}_xG\to\mathrm{T}_{x^n}G$$

does not revert orientation.

Indeed, connect 1 to a given point $y\in G$ by a geodesic path γ, so $\gamma(0)=1$ and $\gamma(1)=y$. Since $\gamma\colon\mathbb{R}\to G$ is a homomorphism, $h(x)=y$ for $x=\gamma(\frac{1}{n})$. In particular the inverse image $h^{-1}\{y\}$ is nonempty for any $y\in G$.

By $(**)$, for a regular value y, each point in the inverse image $h^{-1}\{y\}$ conributes 1 to the degree of h. Hence $(*)$ follows.

It remains to prove $(**)$. Given an element $g\in G$, denote by $L_g,R_g\colon G\to G$ its left and right shifts; that is, $L_g(x)=g{\cdot}x$ and $R_g(x)=x{\cdot}g$. Identify the tangent spaces T_xG and $\mathrm{T}_{x^n}G$ with the Lie algebra $\mathfrak{g}=\mathrm{T}_eG$ using $dR_x\colon\mathfrak{g}\to\mathrm{T}_xG$ and $dR_x^n\colon\mathfrak{g}\to\mathrm{T}_{x^n}G$ correspondingly. Then for any $V\in\mathfrak{g}$, we have

$$d_xh(V)=V+\mathrm{Ad}_x(V)+\dots+\mathrm{Ad}_x^{n-1}(V),$$

where $\mathrm{Ad}_x=d(L_x\circ R_{x^{-1}})\colon\mathfrak{g}\to\mathfrak{g}$. Since the metric on G is bi-invariant, we have $\mathrm{Ad}_x\in\mathrm{SO}(\mathfrak{g})$. It remains to note that the linear transformation

$$V\mapsto V+T(V)+\dots+T^{n-1}(V)$$

can not revert orientation for any $T\in\mathrm{SO}_m$. The last statement is an exercise in linear algebra. $\square$

The idea of this solution is due to Murray Gerstenhaber and Oscar Rothaus [see 164]. In fact the degree of g is n^k, where k is the rank of G [see 165].

Chapter 7

Topology

In this chapter we consider geometrical problems with strong topological flavor. A typical introductory course in topology, say [166], contains all the necessary material.

Isotropy

Recall that an isotopy is a continuous one parameter family of embeddings.

Let K_1 and K_2 be homeomorphic compact subsets of the coordinate subspace $\mathbb{R}^m$ in $\mathbb{R}^{2\cdot m}$. Show that there is a homeomorphism

$$h\colon \mathbb{R}^{2\cdot m} \to \mathbb{R}^{2\cdot m}$$

such that $K_2 = h(K_1)$. Moreover, h can be chosen to be isotopic to the identity map.

Semisolution. Fix a homeomorphism $\varphi\colon K_1 \to K_2$.

By Tietze extension theorem, the homeomorphisms $\varphi\colon K_1 \to K_2$ and $\varphi^{-1}\colon K_2 \to K_1$ can be extended to a continuous maps; denote these maps by $f\colon \mathbb{R}^m \to \mathbb{R}^m$ and $g\colon \mathbb{R}^m \to \mathbb{R}^m$ correspondingly.

Consider the homeomorphisms $h_1, h_2, h_3\colon \mathbb{R}^m \times \mathbb{R}^m \to \mathbb{R}^m \times \mathbb{R}^m$ defined the following way

$$\begin{aligned} h_1(x,y) &= (x, y + f(x)),\\ h_2(x,y) &= (x - g(y), y),\\ h_3(x,y) &= (y, -x). \end{aligned}$$

It remains to observe that each homeomorphism h_i is isotopic to the identity map and

$$K_2 = h_3 \circ h_2 \circ h_1(K_1). \qquad \square$$

The problem is due to Victor Klee [see 167]. The problem “Monotonic homotopy” on page 119 is closely related.

Immersed disks

Two immersions f_1 and f_2 of the disc $\mathbb{D}$ into the plane will be called *essentially different* if there is no diffeomorphism $h\colon \mathbb{D} \to \mathbb{D}$ such that $f_1 = f_2 \circ h$.

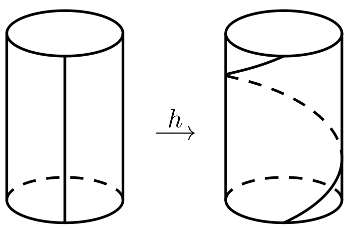
Construct two essentially different smooth immersions of the disk into the plane which coincide near the boundary.

Positive Dehn twist

Let Σ be a surface and

$$\gamma\colon \mathbb{R}/\mathbb{Z} \to \Sigma$$

be non-contractible closed simple curve. Let U_γ be a neighborhood of γ which admits a parametrization



$$\iota\colon \mathbb{R}/\mathbb{Z} \times (0,1) \to U_\gamma.$$

Dehn twist along γ is a homeomorphism $h\colon \Sigma \to \Sigma$ which is identity outside of U_γ and such that

$$\iota^{-1} \circ h \circ \iota\colon (x, y) \mapsto (x + y, y).$$

If Σ is oriented and ι is orientation preserving, then the Dehn twist described above is called *positive*.

Let Σ be an compact oriented surface with nonempty boundary. Prove that any composition of positive Dehn twists of Σ is not homotopic to identity rel. boundary.

In other words, any product of positive Dehn twists is nontrivial in the mapping class group of Σ.

Conic neighborhood

Let p be a point in a topological space X. We say that an open neighborhood $U \ni p$ is *conic* if there is a homeomorphism from a cone to U which sends its vertex to p.

Show that any two conic neighborhoods of one point are homeomorphic to each other.

Unknots°

Prove that the set of smooth embeddings $f\colon \mathbb{S}^1 \to \mathbb{R}^3$ equipped with the C^0-topology forms a connected space.

Stabilization

Construct two compact subsets $K_1, K_2 \subset \mathbb{R}^2$ such that K_1 is not homeomorphic to K_2, but $K_1 \times [0,1]$ is homeomorphic to $K_2 \times [0,1]$.

Homeomorphism of cube

Let $\square^m$ be a cube in $\mathbb{R}^m$ and $h\colon \square^m \to \square^m$ be a homeomorphism which sends each face of $\square^m$ to itself. Extend h to a homeomorphism $f\colon \mathbb{R}^m \to \mathbb{R}^m$ which coincides with the identity map outside of a bounded set.

Finite topological space°

Given a finite topological space F construct a finite simplicial complex K which admits a weak homotopy equivalence $K \to F$.

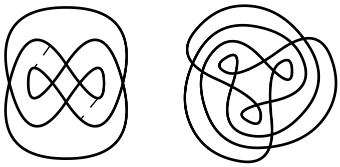
Dense homeomorphism°

Denote by $\mathcal{H}$ be the set of all orientation preserving homeomorphisms $\mathbb{S}^2 \to \mathbb{S}^2$ equipped with the C^0-metric. Show that there is a homeomorphism $h \in \mathcal{H}$ such that its conjugations $a \circ h \circ a^{-1}$ for all $a \in \mathcal{H}$ form a dense set in $\mathcal{H}$.

Simple path°

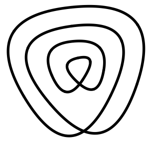
Let p and q be distinct points in Hausdorff topological space X. Assume p and q are connected by a path. Show that they can be connected by a simple path; that is, there is an injective continuous map $\beta\colon [0,1] \to X$ such that $\beta(0) = p$ and $\beta(1) = q$.

Semisolutions



Immersed disks. Both circles on the picture bound essentially different discs.

On the first diagram, the dashed lines and the solid lines together bound three embedded discs; gluing these discs along the dashed lines gives the first immersion. The reflection of this immersion in the vertical line of symmetry gives an other immersion which is essentially different. □



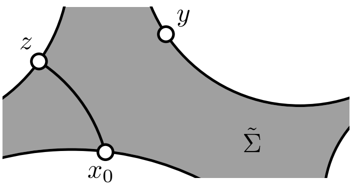
It is a good exercise to count the essentially different discs in the second example. (The answer is 5.)

The existence of examples of that type is generally attributed to John Milnor [see 168].

An easier problem would be to construct two essentially different immersions of annuli with the same boundary curves; a solution is shown on the picture [for more details and references see 169].

Positive Dehn twist. Consider the universal covering $f\colon \tilde\Sigma \to \Sigma$. The surface $\tilde\Sigma$ comes with the orientation induced from Σ.

Fix a point x_0 on the boundary $\partial\tilde\Sigma$. Given two other points y and z in $\partial\tilde\Sigma$ we will write $z \succ y$ if y lies on the right side from some simple curve from x_0 to z in $\tilde\Sigma$. Note that $\succ$ defines a linear order on $\partial\tilde\Sigma\backslash\{x_0\}$. We will write $z \succeq y$ if $z \succ y$ or $z = y$.



Note that any homeomorphism $h\colon \Sigma \to \Sigma$ which is identity on the boundary lifts to the unique homeomorphism $\tilde h\colon \tilde\Sigma \to \tilde\Sigma$ such that $\tilde h(x_0) = x_0$. The following claim is the key step in the proof.

$(*)$ *Assume h is a positive Dehn twist along closed curve γ. Then $y \succeq \tilde h(y)$ for any $y \in \partial\tilde\Sigma\backslash\{x_0\}$ and $y_0 \succ \tilde h(y_0)$ for some $y_0 \in \partial\tilde\Sigma\backslash\{x_0\}$.*

Note that the property in $(*)$ is a homotopy invariant and it survives under compositions of maps. Therefore the problem follows from $(*)$.

If Σ is not an annulus, then by uniformization theorem, we can assume that Σ has hyperbolic metric and geodesic boundary; the lifted metric on $\tilde{\Sigma}$ has the same properties. Further we can assume that (1) γ is a closed geodesic, (2) the parametrization $\iota\colon \mathbb{R}/\mathbb{Z} \times (0,1) \to U_\gamma$ from the definition of Dehn twist is rotationally symmetric and (3) for any $u \in \mathbb{R}/\mathbb{Z}$ the arc $\iota(u \times (0,1))$ is a geodesic perpendicular to γ.

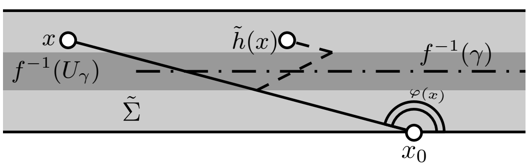
Consider the polar coordinates (φ, ρ) on $\tilde{\Sigma}$ with the origin at x_0; since x_0 lies on the boundary, the angle coordinate φ is defined in $[0, \pi]$. By construction of Dehn twist, we get

$$\varphi(x) \geqslant \varphi \circ \tilde{h}(x)$$

for any $x \neq x_0$ and if the geodesic $[x_0 x]$ crosses $f^{-1}(U_\gamma)$ then

$$\varphi(x) > \varphi \circ \tilde{h}(x).$$

In particular, if x lies on the boundary then $\tilde{h}(x)$ lies on the right side from the geodesic $[x_0 x]$; hence the claim $(*)$ follows.



If Σ is an annulus, then the same argument works except we have to choose a flat metric on Σ. In this case $\tilde{\Sigma}$ is a strip between two parallel lines in the plane, see the diagram. $\square$

The problem was suggested by Rostislav Matveyev.

The statement does not hold for surfaces without boundary. It is instructive to find a counterexample.

Conic neighborhood. Let V and W be two conic neighborhoods of p. Without loss of generality, we may assume that $V \Subset W$; that is, the closure of V lies in W.

We will need to construct a sequence of embeddings $f_n\colon V \to W$ such that

- ◇ For any compact set $K \subset V$ there is a positive integer $n = n_K$ such that $f_n(k) = f_m(k)$ for any $k \in K$ and $m \geqslant n$.
- ◇ For any point $w \in W$ there is a point $v \in V$ such that $f_n(v) = w$ for all large n.

Note that once such sequence is constructed, $f\colon V \to W$ defined as $f(v) = f_n(v)$ for all large values of n gives the needed homeomorphism.

The sequence f_n can be constructed recursively, setting

$$f_{n+1} = \Psi_n \circ f_n \circ \Phi_n,$$

where $\Phi_n \colon V \to V$ and $\Psi_n \colon W \to W$ are homeomorphisms of the form

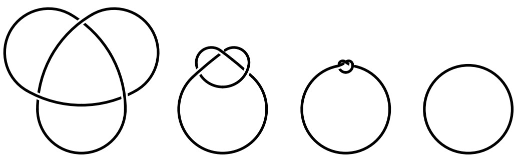
$$\Phi_n(x) = \varphi_n(x)\cdot x \quad \text{and} \quad \Phi_n(x) = \psi_n(x)\cdot x,$$

where $\varphi_n \colon V \to \mathbb{R}_+$, $\psi_n \colon W \to \mathbb{R}_+$ are suitable continuous functions and "$\cdot$" denotes the "multiplication" in the cone structures of V and W correspondingly. $\square$

The problem is due to Kyung Whan Kwun [see 170].

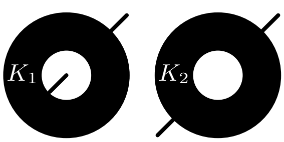
Note that two cones $\mathrm{Cone}(\Sigma_1)$ and $\mathrm{Cone}(\Sigma_2)$ might be homeomorphic while Σ_1 and Σ_2 are not.

Unknots.



Observe that it is possible to draw tight arbitrary knot while keeping it smoothly embedded all the time including the last moment. $\square$

This problem was suggested by Greg Kuperberg.



Stabilization. The example can be guessed from the diagram.

The two sets K_1 and K_2 are subspaces of the plane each is a closed annulus with attached two line segments. In K_1 one segment is attached from inside and the other from the outside and in K_2 both segments are attached from outside.

The product spaces $K_1 \times [0,1]$ and $K_2 \times [0,1]$ are solid toruses with attached rectangles. A homeomorphism $K_1 \times [0,1] \to K_2 \times [0,1]$ can be contrasted by twisting part of one solid torus.

To prove the nonexistence of homeomorphism $K_1 \to K_2$ consider the sets of cut points $V_i \subset K_i$ and the sets $W_i \subset K_i$ of points which admit a punctured simply connected neighborhood. Note that the set V_i is the union of the attached line segments and W_i is the boundary of annulus without points where the segments are attached. Note that $V_i \cup W_i = \partial K_i$; in particular, a homeomorphism $K_1 \to K_2$ (if exists) sends ∂K_1 to ∂K_2.

Finally note that each ∂K_i has two connected components and V_1 lies in both components of ∂K_1 while V_2 lies in one components of ∂K_2. Hence $K_1 \not\cong K_2$. $\square$

I learned this problem from Maria Goluzina around 1988 and I was not been able to trace its origin.

Homeomorphism of cube. Let us extend the homeomorphism h to whole $\mathbb{R}^m$ by reflecting the cube in its facets. We get a homeomorphism say $\tilde{h}\colon \mathbb{R}^m \to \mathbb{R}^m$ such that $\tilde{h}(x) = h(x)$ for any $x \in \square^m$ and

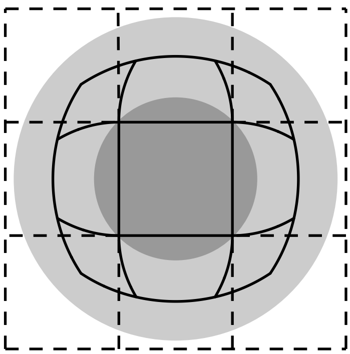
$$\tilde{h} \circ \gamma = \gamma \circ \tilde{h},$$

where γ is any reflection in the facets of the cube.

Without loss of generality, we may assume that the cube $\square^m$ is inscribed in the unit sphere centered at the origin of $\mathbb{R}^m$. In this case $\tilde{h}$ has *displacement* at most 2; that is,

$$|\tilde{h}(x) - x| \leqslant 2$$

for any $x \in \mathbb{R}^m$.



Fix a smooth increasing concave function $\varphi\colon \mathbb{R} \to \mathbb{R}$ such that

$$\varphi(r) = r$$

for any $r \leqslant 1$ and

$$\sup\{\varphi(r)\} = 2.$$

Equip $\mathbb{R}^m$ with the polar coordinates (u, r), where $u \in \mathbb{S}^{m-1}$ and $r \geqslant 0$. Consider the open embedding $\Phi\colon \mathbb{R}^m \hookrightarrow \mathbb{R}^m$ defined as $\Phi(u, r) = (u, \varphi(r))$.

Set

$$f(x) = \left[\begin{array}{ll} x & \text{if } |x| \geqslant 2 \\ \Phi \circ \tilde{h} \circ \Phi^{-1}(x) & \text{if } |x| < 2 \end{array}\right.$$

It remains to observe that $f\colon \mathbb{R}^m \to \mathbb{R}^m$ is a solution. $\square$

The problem is a stripped from a proof of Robion Kirby [see 171]. The condition that face is mapped to face can be removed and instead of homeomorphism one can take an embedding which is close enuf to the identity.

An interesting twist to this idea was given by Dennis Sullivan in [136]. Instead of the discrete group of motions of Euclidean space, he use a discrete group of motions of hyperbolic space in the conformal disk model.

To see the idea, note that the construction of $\tilde{h}$ can be done for a Coxeter polytope in the hyperbolic space instead of cube. Then the constructed map $\tilde{h}$ coincides with the identity on the absolute and therefore the last "shrinking" step in the proof above is not needed. Moreover, if the original homeomorphism is bi-Lipschitz, then the construction also produce a bi-Lipschitz homeomorphism — this is the main advantage.

Finite topological space. Given a point $p \in F$, denote by O_p the minimal open set in F containing p. Note that we can assume that F connected T_0-space; in particular, $O_p = O_q$ if and only if $p = q$.

Let us write $p \preccurlyeq q$ if $O_p \subset O_q$. The relation $\preccurlyeq$ is a partial order on F.

Let us construct a simplicial complex K by taking F as the set of its vertices and saying that a collection of vertices form a simplex if they can be linearly ordered with respect to $\preccurlyeq$.

Given $k \in K$, consider the minimal simplex $(f_0, \dots, f_m) \ni k$; we can assume that $f_0 \preccurlyeq \dots \preccurlyeq f_m$. Set $h\colon k \mapsto f_0$; it defines a map $K \to F$.

It remains to check that h is continuous and induces an isomorphism of all the homotopy groups. □

In a similar fashion, one can construct a finite topological space F for given simplicial complex K such that there is a weak homotopy equivalence $K \to F$. Both constructions are due to Pavel Alexandrov [see 172, 173].

Dense homeomorphism. Note that there is countable set of homeomorphisms $h_1, h_2, \dots$ which is dense in $\mathcal{H}$ such that each h_n fix all the points outside an open round disc, say D_n.

Choose a countable disjoint collection of round discs D'_n and consider the homeomorphism $h\colon \mathbb{S}^2 \to \mathbb{S}^2$ which fix all the points outside of $\bigcup_n D'_n$ and for each n, the restriction $h|_{D'_n}$ is conjugate to $h_n|_{D_n}$.

Note that for large n, the homeomorphism h is conjugate to a homeomorphism close to h_n. Therefore h is a solution. □

The problem was mentioned by Frederic Le Rox [see 174] on a problem section at a conference in Oberwolfach, where he also conjectured that this is not true for the area-preserving homeomorphisms. An affirmative answer to this conjecture was given by Daniel Dore, Andrew Hanlon and Sobhan Seyfaddini [see 175, 176]

Simple path. We will give two solution, first is elementary and the second is involved.

First solution. Let α be a path connecting p to q.

Passing to a subinterval if necessary, we can assume that $\alpha(t) \neq p, q$ for $t \neq 0, 1$.

An open set Ω in $(0, 1)$ will be called *suitable* if for any connected component (a, b) of Ω we have $\alpha(a) = \alpha(b)$. Passing to the union of nested sequence of suitable sets we can find a maximal suitable set $\hat{\Omega}$; that is, $\hat{\Omega}$ suitable and it is not a subset of any other suitable set.

Define $\beta(t) = \alpha(a)$ for any t in a connected component $(a, b) \subset \Omega$. Note that β is continuous and monotonic; that is, for any $x \in [0, 1]$ the set $\beta^{-1}\{\beta(x)\}$ is connected.

It remains to re-parametrize β to make it injective. □

Second solution. Note that one can assume that X coincides with the image of α. In particular X is connected, locally connected, compact Hausdorff space.

Any such space admits a length-metric. This statement is not at all trivial; it was conjectured by Karl Menger in [177] and proved independently by R. H. Bing [see 178, 179] and Edwin Moise [see 180].

It remains to consider a geodesic path from p to q. □

The problem inspired by a lemma proved by Alexander Lytchak and Stefan Wenger [see 7.13 in 181].

Chapter 8

Piecewise linear geometry

A *polyhedral space* is complete length-metric space which admits a locally finite triangulation such that each simplex is isometric to a simplex in a Euclidean space. By *triangulation* of polyhedral space we always understand triangulation as above.

A point in a polyhedral space is called *regular* if it has a neighborhood isometric to an open set in a Euclidean space; otherwise it called *singular*.

If we would exchange the Euclidean spaces to the unit spheres or the hyperbolic spaces, we arrive to the definition of *spherical* and *hyperbolic polyhedral spaces* correspondingly.

The term *piecewise* typically mean that there is a triangulation with some property on each triangle. For example, if P and Q are polyhedral spaces, then

- ◇ a map $f\colon P \to Q$ is called *piecewise distance preserving* if there is a triangulation $\mathcal{T}$ of P such that at any simplex $\Delta \in \mathcal{T}$ the restriction $f|_\Delta$ is distance preserving,
- ◇ a map $h\colon P \to Q$ is called *piecewise linear* if both spaces P and Q admit triangulations such that each simplex of P is mapped to a simplex of Q by an affine map. In particular, a *piecewise linear homeomorphism* is a piecewise linear map which is a homeomorphism.

Spherical arm lemma

Let $A = a_1a_2\dots a_n$ and $B = b_1b_2\dots b_n$ be two simple spherical polygons with equal corresponding sides. Assume A lies in a hemisphere and $\measuredangle a_i \geqslant \measuredangle b_i$ for each i. Show that A is congruent to B.

Semisolution. Let us cut the polygon A from the sphere and glue instead the polygon B. Denote by Σ the obtained spherical polyhedral space. Note that

- $\diamond$ Σ is homeomorphic $\mathbb{S}^2$.
- $\diamond$ Σ has curvature $\geqslant 1$ in the sense of Alexandrov; that is, the total angle around each singular point is less than $2{\cdot}\pi$.
- $\diamond$ All the singular points of Σ lie outside of an isometric copy of a hemisphere $\mathbb{S}^2_+ \subset \Sigma$

Denote by n the number of singular points in Σ. It is sufficient to show that $n = 0$.

Assume the contrary; that is, $n \geqslant 1$. We will arrive to a contradiction applying induction on n. The base case $n = 1$ is trivial; that is, Σ cannot have single singular point.

Now assume Σ has $n > 1$ singular points. Choose two singular points p, q, cut Σ along a geodesic $[pq]$. The hole can be patched so that we obtain a new polyhedral space Σ' of the same type but with $n - 1$ singular points. Namely, if the total angles around p and q are $2{\cdot}\pi - \alpha$ and $2{\cdot}\pi - \beta$ correspondingly, consider the spherical triangle $\triangle$ with base $|p - q|_\Sigma$ and adjusted angles $\frac{\alpha}{2}$, $\frac{\beta}{2}$. The needed patch is obtained by doubling $\triangle$ along its lateral sides.

By induction hypothesis Σ' does not exist. Hence the result follows. $\square$

Alternative end of proof. By Alexandrov embedding theorem, Σ is isometric to the surface of convex polyhedron P in the unit 3-dimensional sphere $\mathbb{S}^3$. The center of hemisphere has to lie in a facet, say F of P. It remains to note that F contains the equator and therefore P has to be hemisphere in $\mathbb{S}^3$ or intersection of two hemispheres. In both cases its surface is isometric to $\mathbb{S}^2$. $\square$

The problem is due to Victor Zalgaller [see 182]; the result of Victor Toponogov in [183] gives a smooth analog of this statement. The patch construction above was introduced by Aleksandr Alexandrov in his proof of convex embeddability of polyhedrons [see 184, VI, §7]. The alternative end of proof is taken from [112].

Triangulation of 3-sphere

Construct a triangulation of $\mathbb{S}^3$ *with* 100 *vertices such that any two vertices are connected by an edge.*

Folding problem

📖 *Let P be a compact 2-dimensional polyhedral space. Construct a piecewise distance preserving map $f\colon P\to\mathbb{R}^2$.*

Piecewise distance preserving extension

📖 *Prove that any 1-Lipschitz map from a finite subset $F\subset\mathbb{R}^2$ to $\mathbb{R}^2$ can be extended to a piecewise distance preserving map $\mathbb{R}^2\to\mathbb{R}^2$.*

Closed polyhedral surface

📖 *Construct a closed polyhedral surface in $\mathbb{R}^3$ with nonpositive curvature; that is, the total angle around each vertex is at least $2{\cdot}\pi$.*

Minimal polyhedral disc

By a polyhedral disc in $\mathbb{R}^3$ we understand a triangulation of a plane polygon with a map in $\mathbb{R}^3$ which is affine on each triangle. The area of the polyhedral disc is defined as the sum of areas of the images of the triangles in the triangulation.

📖 *Consider the class of polyhedral discs glued from n triangles in $\mathbb{R}^3$ with fixed broken line as the boundary. Let Σ_n be a disc of minimal area in this class. Show that Σ_n is* saddle*; that is, a plane can not cut all the edges coming from one of the interior vertices of Σ_n.*

Coherent triangulation°

A triangulation of a convex polygon is called coherent if there is a convex function which is linear on each triangle and changes the gradient on every edge of the triangulation.

📖 *Find a non-coherent triangulation of a triangle.*

Sphere with one edge*

Given a polyhedral space P, denote by P_s the subset of its singular points.

📖 *Construct spherical polyhedral space P which is homeomorphic to $\mathbb{S}^3$ such that P_s is formed by a knotted circle.*

Triangulation of a torus

Show that the torus does not admit a triangulation such that one vertex has 5 edges, one has 7 edges and all other vertices have 6 edges.

No simple geodesics°

Construct a convex polyhedron P whose surface does not have a closed simple geodesic.

Semisolutions

Triangulation of 3-sphere. Choose 100 distinct points $p_1, p_2, \dots$ $\dots, p_{100}$ on the *moment curve*

$$\gamma\colon t \mapsto (t, t^2, t^3, t^4)$$

in $\mathbb{R}^4$. Let P be the convex hull of $\{p_1, p_2, \dots, p_{100}\}$.

The surface of P is homeomorphic to $\mathbb{S}^2$. Therefore it is sufficient to show that any two vertexes of P are connected by an edge. The letter follows from the following claim.

($*$) *For any two points p and q on γ there is a hyperplane H in $\mathbb{R}^4$ which intersects γ only at p and q and leaves γ on one side.*

To prove the claim, assume that $p = \gamma(t_1)$ and $q = \gamma(t_2)$. Consider the polynomial

$$f(t) = a + b{\cdot}t + c{\cdot}t^2 + d{\cdot}t^3 + t^4 = (t - t_1)^2{\cdot}(t - t_2)^2.$$

Clearly $f(t) \geqslant 0$ and the equality holds only at t_1 and t_2. It follows that the affine function $\ell\colon \mathbb{R}^4 \to \mathbb{R}$ defined as

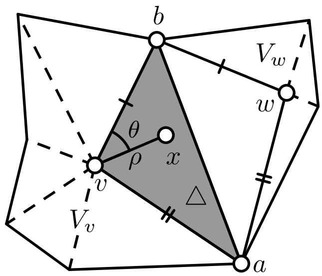
$$\ell\colon (w, x, y, z) \mapsto a + b{\cdot}w + c{\cdot}x + d{\cdot}y + z$$

is nonnegative at the points of γ and vanish only at p and q. Therefore the zero set of ℓ is the required hyperplane H in ($*$). $\square$

The polyhedron P above is an example of so called *cyclic polytopes.*

Folding problem. Given a triangulation of P, consider the Voronoi domain V_v for each vertex v; that is, V_v is the set of all points in P closer to v than to any other vertex. Note that the triangulation can be subdivided if necessary so that Voronoi domain of each vertex is isometric to a convex subset in the cone with vertex corresponding to the tip.

Note that the boundaries of all the Voronoi domains form a graph with straight edges. Let us triangulate P so that each triangle has such edge as the base and the opposite vertex is the center of an adjusted Voronoi domain; such a vertex will be called *main* vertex of the triangle.



Fix a solid triangle $\triangle = [vab]$ in the constructed triangulation; let v be its main vertex. Given a point $x \in \triangle$, set

$$\rho(x) = |x - v|$$

and

$$\theta(x) = \min\{\measuredangle[v\,{}^a_x], \measuredangle[v\,{}^b_x]\}.$$

Let us map x to the point with polar coordinates $(\rho(x), \theta(x))$ in the plane.

Note that for each triangle $\triangle$, the constructed map $\triangle \to \mathbb{R}^2$ is piecewise distance preserving. It remains to check that these maps agree on the common sides of the triangles. $\square$

This construction was given by Victor Zalgaller [see 185]. Svetlana Krat generalized the statement to the higher dimensions [see 186].

Piecewise distance preserving extension. Let $a_1, a_2, \dots, a_n$ and b_1, $b_2, \dots, b_n$ be two collections of points in $\mathbb{R}^2$ such that $|a_i - a_j| \geqslant |b_i - b_j|$ for all pairs i, j. We need to construct a piecewise distance preserving map $f\colon \mathbb{R}^2 \to \mathbb{R}^2$ such that $f(a_i) = b_i$ for each i.

Assume that the problem is already solved if $n < m$; let us do the case $n = m$. By assumption, there is a piecewise liner length-preserving map $f\colon \mathbb{R}^2 \to \mathbb{R}^2$ such that $f(a_i) = b_i$ for each $i > 1$.

Consider the set

$$\Omega = \left\{\, x \in \mathbb{R}^2 \,\middle|\, |f(x) - b_1| > |x - a_1| \,\right\}.$$

Since $|a_i - a_1| \geqslant |b_i - b_1|$, we get $a_i \notin \Omega$ for $i > 0$.

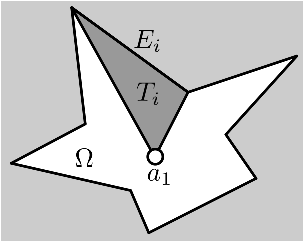
Note that we can assume that the map f and therefore the set Ω are bounded. Indeed, let $\square$ be a square containing all the points b_i. There is a piecewise isometric map $h\colon \mathbb{R}^2 \to \square$ which can be obtained by folding plane along the lines of the grid defined by $\square$. Then the composition $h \circ f$ is bounded and it satisfies all the properties of f described above.

If $\Omega = \varnothing$, then $f(a_1) = b_1$; that is, f is a solution. It remains to consider the case $\Omega \neq \varnothing$.

Note that Ω is star-shaped with respect to a_1. Indeed, if $x \in \Omega$, then $|a_1 - x| < |b_1 - f(x)|$. If $y \in [a_1 x]$ then $|a_1 - y| + |y - x| = |a_1 - x|$

and since f is length-preserving we get $|f(x) - f(y)| \leqslant |x - y|$. By the triangle inequality, $|a_1 - y| < |b_1 - f(y)|$; that is, $y \in \Omega$.

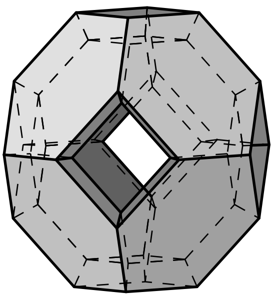
The boundary $\partial\Omega$ can be subdivided into finite collection of line segments $\{E_i\}$ so that the map f rigidly each E_i. Note that $|f(x) - b_1| = |x - b_1|$ for any $x \in E_i$. Denote by T_i the triangle with base E_i and vertex a_1. From above there is a rigid motion m_i of T_i such that $m_i(x) = f(x)$ for any $x \in E_i$ and $m_i(a_1) = b_1$. Let us redefine the map f in Ω by sending x to $m_i(x)$ for $x \in T_i$. This way we produce a new piecewise isometric map $f' : \mathbb{R}^2 \to \mathbb{R}^2$ which satisfies all the requirements. $\square$



The same proof works in all dimensions.

The statement was proved by Ulrich Brehm in [187] and rediscovered by Arseniy Akopyan and Alexey Tarasov in [188], see also [143]. The idea in the proof is the same as in the proof of Kirszbraun's theorem given in [31].

Closed polyhedral surface. An example can be constructed by drilling a polyhedral cave from a you favorite convex polyhedron. On the diagram you see the result of this construction for the octahedron.

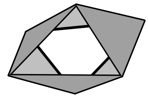


Choose a convex polyhedron K. We can assume that the interior of K contains the origin $0 \in \mathbb{R}^3$. Remove from K the interior of $K' = \frac{5}{6} \cdot K$.

Note that one can drill from each vertex of K a polyhedral tunnel to the corresponding vertex K' so that the surface of obtained non-convex polytope is a solution. $\square$

The problem suggested by Jarosław Kędra.

The construction above produce a surface of genus at least 3. One can also construct a polyhedral surface in $\mathbb{R}^3$ which is isometric to a flat torus. The existence of such torus follows from very general result of Burago and Zalgaller [see 189]. They show in particular that any 1-Lipschitz smooth embedding of flat torus in $\mathbb{R}^3$ can be approximated by piecewise distance preserving embedding.



The following construction is more direct; it is a bent version of so called *Schwarz boot* [see 190]. Construct an isometric piecewise linear embedding of cylinder from six triangles as on the diagram in such a way that the planes thru the boundary triangles meet at the angle $\frac{\pi}{n}$ for a positive integer n. It remains to reflect the obtained surface several times in the planes thru the boundary triangles.

The following related problem was proposed by Brian Bowditch; a solution can be build on the construction of Joel Hass [see 191].

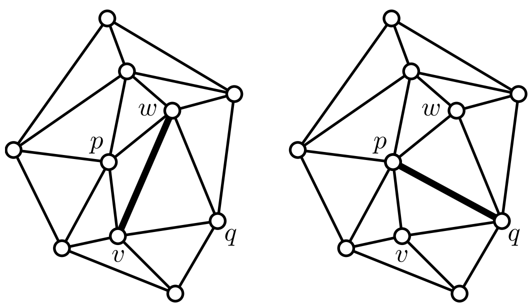
Construct a polyhedral metric on 3-sphere such that the total angle around any edge of its triangulation is at least $2{\cdot}\pi$.

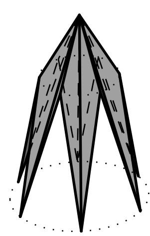
Minimal polyhedral disc. Arguing by contradiction, assume a polyhedral disc Σ minimize the area but not saddle; that is, there is an interior vertex v of Σ such that all the edges from v can be cut by a plane.

Note that we can move v in such a way that the lengths of all its edges decrease.

Since the area is minimal, this deformation does not decease the area. Taking the derivative of the total area in along this deformation implies that Σ contains two adjusted non-coplanar triangles $[pvw]$ and $[qvw]$ such that

$$\measuredangle[p\,{}^{v}_{w}]+\measuredangle[q\,{}^{v}_{w}]>\pi.$$





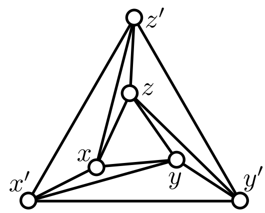
In this case exchanging triangles $[pvw]$ and $[qvw]$ to the triangles $[vpq]$ and $[wpq]$ leads to a polyhedral surface with smaller area. That is, Σ is not area minimizing, a contradiction. □

This problem is discussed in [192].

For general polyhedral surface, the deformation which decrease the lengths of all edges may not decrease the area. Moreover, the surface which minimize the area among all surfaces with fixed triangulation might be not saddle; an example is shown on the diagram.

Coherent triangulation. An example shown on the diagram. The triangulation of triangle $[x'y'z']$ has a homothetic triangles $[xyz]$ and the edges $[xx']$, $[yy']$, $[zz']$, $[yx']$, $[zy']$, $[xz']$.

Assume that this triangulation is coherent; let f be the corresponding piecewise linear convex function. Without loss of generality we can assume that f vanish on the boundary of big triangle.



From convexity of f at the edges $[x'y]$, $[y'z]$ and $[z'x]$, we get

$$f(x) > f(y) > f(z) > f(x),$$

a contradiction. □

The problem was discussed in the book of Israel Gelfand, Mikhail Kapranov and Andrei Zelevinsky [see 7C in 193]. The given example is closely related to the so called *Schönhardt polyhedron*, an example of non-convex polyhedron which does not admit a triangulation [see 194].

Sphere with one edge. An example P can be found among polyhedral spaces with isometric $\mathbb{S}^1$ action which has geodesic orbits. (Equivalently the cone over P admits a complex structure, that is one can cut simplicies from $\mathbb{C}^2$ and glue the cone from them so that the complex structures agree on the gluing.)

Let us identify $\mathbb{S}^3$ with the unit sphere in the hyperplane Π described $x + y + z = 0$ of $\mathbb{C}^3$. The symmetric group S_3 acts on $\mathbb{S}^3$ by permuting the coordinates. Take $P = \mathbb{S}^3/S_3$.

Note that P is a polyhedral space. Moreover, P is an underlying space for an orbifold which isotopy groups either trivial or $\mathbb{Z}_2$. In particular P is a 3-manifold. Clearly P is compact and simply connected, in particular it is homeomorphic to 3-sphere. The later can be also seen by parametrizing P using the symmetric polynomials $u = xy+yz+zx$ and $v = xyz$.

Multiplications by unit complex numbers give an $\mathbb{S}^1$-action on $\mathbb{S}^3$ which commutes with the S_3-action. The singular set P_s of P is the image of the orbit $\mathbb{S}^1{\cdot}p$ where p is a point fixed by an odd permutation of S_3. In particular P_s is a circle.

Note that the subgroup of even permutations $\mathbb{Z}_3 \lhd S_3$ acts freely on $\mathbb{S}^3$. The quotient space $\mathbb{S}^3/\mathbb{Z}_3$ is the double cover of P branching in P_s. That is, a double cover of the sphere P branching in the knot P_s is not simply connected. Therefore P_s is a nontrivial knot.

(In fact P_s is a trefoil and in the (u, v) coordinates it can be written as $u^3 = v^2$.) □

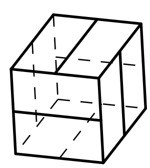
This construction is given by Dmitri Panov in [195].

Note that the quotient space $P' = P/\mathbb{S}^1$ is isometric to the doubling of triangle in $\mathbb{C}\mathrm{P}^1 = \mathbb{S}^3/\mathbb{S}^1$ with the angles $\frac{\pi}{2}$, $\frac{\pi}{2}$ and $\frac{\pi}{3}$. Starting with other triangles one may produce P with isometric $\mathbb{S}^1$ and arbitrary torus knot as the singular set. It can also produce arbitrary long singular sets. In these examples, the cone over P can be holomorphically parametrized by $\mathbb{C}^2$ in such a way that its singular set becomes an algebraic curve $u^p = v^q$ in some (u, v)-coordinates of $\mathbb{C}^2$. Here is a related problem.

Construct a complex orbifold with the underlying space homeomorphic to $\mathbb{C}\mathrm{P}^2$.

The solution of the problem gives the polyhedral metric on $\mathbb{C}\mathrm{P}^2$ with nonnegative curvature in the sense of Alexandrov. It is not know if the canonical metric on $\mathbb{C}\mathrm{P}^2$ can be approximated by such polyhedral metrics.

I do not know if such knots exist for Euclidean polyhedral spaces, but there are links. For example, the Borromean rings can appear as the singular set of a Euclidean polyhedral metrics on $\mathbb{S}^3$. It can be obtained by gluing each face of cube to it self along the reflections in the middle lines shown on the picture. This construction is due to William Thurston [see 196]



Triangulation of a torus. Assume contrary; let τ be a trainagulation of the torus with vertex z_5 which meets 5 triangles, vertex z_7 which meets 7 triangles and every other vertex meets 6 triangles.

Let us equip the torus with the flat metric such that each triangle is equilateral. The metric will have two singular cone points z_5 and z_7. The total angle around z_5 is $\frac{5}{3}{\cdot}\pi$ and the total angle around z_7 is $\frac{7}{3}{\cdot}\pi$. Note the following.

(∗) *The holonomy group of the obtained polyhedral metric on the torus is generated by rotation by* $\frac{\pi}{3}$.

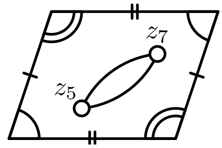
Indeed, since the parallel translation along any loop preserves the directions of the sides of triangle; it can only permute it cyclically, which corresponds to rotations by multiple of $\frac{\pi}{3}$. On the other hand, the holonomy of the loop which surrounds z_5 is a rotation by $\frac{\pi}{3}$.

Consider a closed geodesic γ_1 which minimize the length of all circles which are not null-homotopic. Let γ_2 be an other closed geodesic which minimize the length and is not homotopic to any power of γ_1.

Note that γ_1 and γ_2 intersect at a single point. Otherwise one could shorten one of them keeping the defining property.

Note that γ_i does not pass z_5. Infact no geodesic can pass singular point with total angle smaller than $2\cdot\pi$.

Assume γ_i passes thru z_7. Then by $(*)$, one of two angles which γ_i cuts at z_7 equals to π. It follows that one can push γ_i aside so it does not longer pass thru z_7, but remains to be a closed geodesic with the same length.

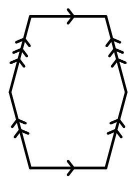


Cut $\mathbb{T}^2$ along γ_1 and γ_2. In the obtained quadrilateral, connect z_5 to z_7 by a minimizing geodesic and cut along it. This way we obtain an annulus Ω with flat metric.

Note that the neighborhood of the first boundary component is parallelogram — it has equal opposite sides and angles which add up to $2\cdot\pi$. In particular Ω admits an isometric immersion into the plane.

The second component has to be mapped to a diangle with straight sides and angles $\frac{\pi}{3}$. Such diangle does not exist in the plane, a contradiction. $\square$

There are flat metrics on the torus with only two singular points which have the total angles $\frac{5}{3}\cdot\pi$ and $\frac{7}{3}\cdot\pi$. Such example can be obtained by identifying the hexagon on the picture according to the arrows. However, the holonomy group of the obtained torus is generated by the rotation by angle $\frac{\pi}{6}$. In particular, the observation $(*)$ is essential in the proof.



The same argument shows that holonomy group of flat torus with exactly two singular points with total angle $2\cdot(1\pm\frac{1}{n})\cdot\pi$ has more than n elements. In the solution we did the case $n=6$.

If one denotes by v_m the number of vertexes in a triangulation of torus with m incoming edges, then by Euler's formula, we get

$$(**)\qquad \sum_m (m-6)\cdot v_m = 0.$$

Note that this equation says nothing about v_6. It turns out that for almost any sequence $v_3, v_4, \dots$ satisfying $(**)$ one can adjust v_6 so that it corresponds to a triangulation of torus — the sequence

$$0, 0, 1, v_6, 1, 0, 0, \dots$$

discussed in the problem is the only exception.

The problem was originally discovered and solved by Stanislav Jendrol' and Ernest Jucovič, in [197], their proof is combinatorial. The solution described above was given by Rostislav Matveyev in his lectures [see 198]. A complex-analytic proof was found by Ivan Izmestiev, Robert Kusner, Günter Rote, Boris Springborn and John Sullivan [see 199].

No simple geodesics. The curvature of a vertex on the surface of a convex polyhedron is defined as the $2\cdot\pi - \theta$, where θ is the total angle around the vertex.

By Gauss–Bonnet formula, a simple closed geodesic cuts the surface into two discs with total curvature $2\cdot\pi$ each. Therefore it is sufficient to construct a convex polyhedron with curvatures of the vertices $\omega_1, \omega_2, \dots, \omega_n$ such that $2\cdot\pi$ cannot be obtained as sum of some of ω_i. An example of that type can be found among the tetrahedrons. □

The problem is due to Gregory Galperin [see 200] and rediscovered by Dmitry Fuchs and Serge Tabachnikov [see 20.8 in 17]. If the surface of P contains arbitrary long closed simple geodesic, then P is *isosceles tetrahedron*; that is, a tetrahedron with equal opposite edges. This statement was was proved by Vladimir Protasov in [201] and generalized for arbitrary convex bodies in [202].

Chapter 9

Discrete geometry

In this chapter we consider geometrical problems with strong combinatoric flavor. No special prerequisite is needed.

Round circles in $\mathbb{S}^3$

Suppose that you have a finite collection of pairwise linked round circles in the unit 3-sphere, not necessarily all of the same radius. Prove that there is an isotopy of the collection of circles which moves all of them into great circles.

Semisolution. For each circle consider the plane containing it. Note that the circles are linked if and only if the corresponding planes intersect at a single point inside the unit sphere $\mathbb{S}^3 \subset \mathbb{R}^4$.

Take the intersection of the planes with the sphere of radius $R \geqslant 1$, rescale and pass to the limit as $R \to \infty$. This way we get needed isotopy. $\square$

The problem was discussed by Genevieve Walsh in [203].

Box in a box

Assume that a parallelepiped with sizes a, b, c lies inside another parallelepiped with sizes a', b', c'. Show that

$$a' + b' + c' \geqslant a + b + c.$$

Harnack's circles

Prove that a smooth algebraic curve of degree d in $\mathbb{RP}^2$ consists of at most $n = \frac{1}{2}\cdot(d^2 - 3\cdot d + 4)$ connected components.

Two points on each line

Construct a set in the Euclidean plane, which intersects each line at exactly 2 points.

Balls without gaps

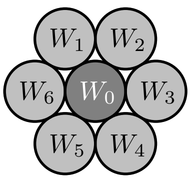
Let $B_1, \dots, B_n$ be the balls of radiuses $r_1, \dots, r_n$ in a Euclidean space. Assume that no hyperplane divides the balls into two non-empty sets without intersecting at least one of the balls. Show that the balls $B_1, \dots, B_n$ can be covered by a ball of radius $r = r_1 + \dots + r_n$.

Covering lemma

Let $\{B_i\}_{i\in F}$ be any finite collection of balls in m-dimensional Euclidean space. Show that there is a subcollection of pairwise disjoint balls $\{B_i\}_{i\in G}$, $G \subset F$ such that

$$\operatorname{vol}\left(\bigcup_{i\in F} B_i\right) \leqslant 3^m \cdot \operatorname{vol}\left(\bigcup_{i\in G} B_i\right).$$

Kissing number°



Let W_0 be a convex body in $\mathbb{R}^m$. We say that k is the *kissing number* of W_0 (briefly $k = \operatorname{kiss} W_0$) if k the maximal integer such that there are k bodies $W_1, W_2, \dots, W_k$ such that (1) each W_i is congruent to W_0, (2) $W_i \cap W_0 \neq \varnothing$ for each i and (3) no pair W_i, W_j has common interior points.

As you may guess from the diagram, the kissing number of round disc in the plane is 6.

Show that for any convex body W_0 in $\mathbb{R}^m$

$$\operatorname{kiss} W_0 \geqslant \operatorname{kiss} B,$$

where B denotes the unit ball in $\mathbb{R}^m$.

Monotonic homotopy

Let F be a finite set and $h_0, h_1\colon F\to\mathbb{R}^m$ be two maps. Consider $\mathbb{R}^m$ as a subspace of $\mathbb{R}^{2\cdot m}$. Show that there is a homotopy $h_t\colon F\to\to\mathbb{R}^{2\cdot m}$ from h_0 to h_1 such that the function

$$t\mapsto |h_t(x)-h_t(y)|$$

is monotonic for any pair $x,y\in F$.

Cube

Half of the vertices of an m-dimensional cube are colored in white and the other half in black. Show that the cube has at least 2^{m-1} edges which connect the vertices of different colors.

Geodesic loop

Show that the surface of cube in $\mathbb{R}^3$ does not admit a geodesic loop with the base point at a vertex.

Right and acute triangles

Let $x_1,\dots,x_n\in\mathbb{R}^m$ be a collection of points such that any triangle $[x_ix_jx_k]$ is right or acute. Show that $n\leqslant 2^m$.

Right-angled polyhedron$^+$

A polyhedron is called *right-angled* if all its dihedral angles are right.

Show that in all sufficiently large dimensions, there is no compact convex hyperbolic right-angled polyhedron.

Let us give a short summary of Dehn–Sommerville equations which can help you to solve this problem.

Assume P is a *simple* Euclidean m-dimensional polyhedron; that is, every vertex of P exactly m facets are meeting. Denote by f_k the number of k-dimensional faces of P; the array of integers $(f_0,f_1,\dots f_m)$ is called f-vector of P.

Fix an order of the vertices $v_1,v_2,\dots,v_{f_0}$ of P so that for some linear function ℓ, we have $\ell(v_i)<\ell(v_j)\ \Leftrightarrow\ i<j$. The *index* of the vertex v_i is defined as the number of edges $[v_iv_j]$ such that $i<j$. The number of vertices of given index k will be denoted as h_k. The array of

integers $(h_0, h_1, \dots h_m)$ is called h-vector of P. Clearly $h_0 = h_m = 1$ and

$$(*)\qquad h_k \geqslant 0 \quad \text{for all} \quad k.$$

Each k-face of P contains unique vertex which maximize ℓ; if the vertex has index i, then $i \geqslant k$ and then it is the maximal vertex for exactly $\frac{i!}{k!\cdot(i-k)!}$ faces of dimension k. This observation can be packed in the following polynomial identity

$$\sum_k h_k\cdot(t+1)^k = \sum_k f_k\cdot t^k.$$

Note that the identity above implies that h-vector does not depend on the choice of order of the vertices. In particular, the h vector is the same for the reversed order; that is

$$(**)\qquad h_k = h_{m-k}$$

for any k.

The identities $(**)$ are called Dehn–Sommerville equations. It gives the complete list of linear equations for h-vectors (and therefore f-vectors) of simple polyhedrons. Note also that the inequalities $(*)$ can be rewritten in terms of f-vectors.

Semisolutions

Box in a box. Let Π be a parallelepiped with dimensions a, b and c. Denote by $v(r)$ the volume of r-neighborhoods of Π,

Note that for all positive r we have

$$(*)\qquad v_\Pi(r) = w_3(\Pi) + w_2(\Pi)\cdot r + w_1(\Pi)\cdot r^2 + w_0(\Pi)\cdot r^3,$$

where

- ◇ $w_0(\Pi) = \frac{4}{3}\cdot\pi$ is the volume of unit ball,
- ◇ $w_1(\Pi) = \pi\cdot(a+b+c)$,
- ◇ $w_2(\Pi) = 2\cdot(a\cdot b + b\cdot c + c\cdot a)$ is the surface area of Π,
- ◇ $w_3(\Pi) = a\cdot b\cdot c$ is the volume of Π,

Assume Π' be an other parallelepiped with dimensions a', b' and c'. If $\Pi \subset \Pi'$, then $v(r)_\Pi \leqslant v_{\Pi'}(r)$ for any r. For $r \to \infty$, these inequalities imply

$$a + b + c \leqslant a' + b' + c'. \qquad \square$$

The problem was discussed by Alexander Shen in [204].

A formula analogous to $(*)$ holds for arbitrary convex body B in arbitrary dimension m. The coefficient $w_i(B)$ in the polynomial with different normalization constants appear under different names most commonly *intrinsic volumes* and *quermassintegrals*. They also can be defined as the average of area of projections of B to the i-dimensional planes. In particular, if B' and B are convex bodies such that $B' \subset B$, then $w_i(B') \leqslant w_i(B)$ for any i. This generalize our problem quite a bit. Further generalizations lead to so called *mixed volumes* [see 205].

Harnack's circles. Let $\sigma \subset \mathbb{R}\mathrm{P}^2$ be a algebraic curve of degree d. Consider the complexification $\Sigma \subset \mathbb{C}\mathrm{P}^2$ of σ. Without loss of generality, we may assume that Σ is regular.

Note that all regular complex algebraic curves of degree d in $\mathbb{C}\mathrm{P}^2$ are isotopic to each other in the class of algebraic curves of degree d. Indeed, the set equation of degree d which correspond to singular curves have the real codimesion 2. Therefore the set of equation of degree d which correspond to regular curves is connected. In particular one can construct isotopy from one regular curve to an other by changing continuously the parameters of their equations.

In particular it follows that all regular complex algebraic curves of degree d in $\mathbb{C}\mathrm{P}^2$ have the same genus, denote it by g. Perturbing a singular curve formed by d lines in $\mathbb{C}\mathrm{P}^2$, we can see that

$$g = \tfrac{1}{2}\cdot(d-1)\cdot(d-2).$$

The real curve σ forms the fixed point set in Σ by the complex conjugation. In particular σ divides Σ into two symmetric surfaces with boundary formed by σ. It follows that each connected component of σ adds one to the genus of Σ. Hence the result follows. $\square$

The inequality was originally proved by Axel Harnack using a different method [see 206]. The idea to use complexification is due to Felix Klein [see 207]. This problem formed the background to Hilbert's 16th problem.

Two points on each line. Take any complete ordering of the set of all lines so that each beginning interval has cardinality less than continuum.

Assume we have a set of points X of cardinality less than continuum such that each line intersects X at most 2 points and cardinality of X is less than continuum.

Choose the least line ℓ in the ordering which intersect X by 0 or 1 point. Note that the set of all lines intersecting X at two points has cardinality less than continuum. Therefore we can choose a point on ℓ and add it to X so that the remaining lines are not overloaded.

It remains to apply well ordering principle. □

This problem has endless list of variations. The following problem look similar but far more involved; a solution follows from the proof that a square cannot be cut into triangles of equal area given given by Paul Monsky in [208].

Subdivide the plane into three everywhere dense sets A, B and C such that each line meets exactly two of these sets.

Balls without gaps. Assume that each ball has the mass proportional to its radius. Denote by z the center of mass of the balls. It is sufficient to show the following.

The ball $B(z, r)$ contains all $B_1, \dots, B_n$.

Assume this is not the case. Then there is a line ℓ thru z, such that the orthogonal projection of some ball B_i to ℓ does not lie in the projection of B completely. (This projection reduces the problem to one-dimensional case.)

Note that the projection of all balls $B_1, \dots, B_n$ has to be connected and it contain a line segment longer than r on one side from z. In this case, the center of mass of balls projects inside of this segment, a contradiction. □

The statement was conjectured by Paul Erdős. The solution is given by Adolph and Ruth Goodmans in [209]. A variation was given later by Hugo Hardwiger in [210].

Covering lemma. The construction of the required collection $\{B_i\}_{i\in G}$ use the *greedy algorithm*. We choose the balls one by one; on each step we take the largest ball which does not intersect those which we choose already.

Note that each ball in the original collection $\{B_i\}_{i\in F}$ intersects a ball in $\{B_i\}_{i\in G}$ with larger radius. Therefore

$$(*) \qquad \bigcup_{i\in F} B_i \subset \bigcup_{i\in G} 3{\cdot}B_i,$$

where $3{\cdot}B_i$ denotes the ball with the came center as B_i and with three times larger radius. Hence the statement follows. □

The constant 3^n is not optimal. The optimal constant is at least 2^n, but its value is not known and maybe no one is willing to know.

The inclusion $(*)$ is called *Vitali covering lemma*. The following statement is so called *Besikovitch covering lemma*; it has a similar proof.

🕮 *For any positive integer m there is a positive integer M such that any finite collection of balls $\{B_i\}_{i\in F}$ in the m-dimensional Euclidean space contains a subcollection $\{B_i\}_{i\in G}$ such that center of any ball from $\{B_i\}_{i\in F}$ lies in one of the balls from $\{B_i\}_{i\in G}$ and the collection $\{B_i\}_{i\in G}$ can be subdivided into M subcollections of pairwise disjoint balls.*

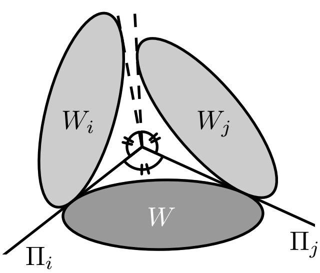
Both lemmas used to prove so called *covering theorems* in measure theory, which state that "undesirable sets" have vanishing measure. Their applications overlap but not identical, *Vitali covering theorem* works for nice measures in arbitrary metric spaces while *Besikovitch covering theorem* work in nice metric spaces for arbitrary Borel measures.

More precisely, Vitali works in arbitrary metric space for so called *doubling measure* μ; which means that

$$\mu B(x,2\cdot r) \leqslant C\cdot \mu B(x,r)$$

for some fixed constant C and any ball $B(x,r)$ in the metric space. On the other hand, Besikovitch works for all Borel measures in the so called *directionally limited* metric spaces [see 2.8.9 in 211]; these include Alexandrov spaces with curvature bounded below.

Kissing number. Fix the dimension m. Set $n = \operatorname{kiss} B$. Let $B_1, B_2, \dots, B_n$ the copies of the ball B which touch B and have no common interior points. For each B_i consider the vector v_i from the center of B to the center of B_i. Note that $\measuredangle(v_i, v_j) \geqslant \frac{\pi}{3}$ if $i \neq j$.



For each i, consider supporting hyperplane Π_i to W with outer normal vector v_i. Denote by W_i the reflection of W in Π_i.

Note that W_i and W_j have no common interior points if $i \neq j$; the latter gives the needed inequality. □

The proof is given by Charles Halberg, Eugene Levin and Ernst Straus in [212]. It is not known if the same inequality holds for the orientation-preserving version of kissing number.

Monotonic homotopy. Note that we can assume that $h_0(F)$ and $h_1(F)$ both lie in the coordinate m-spaces of $\mathbb{R}^{2\cdot m} = \mathbb{R}^m \times \mathbb{R}^m$; that is, $h_0(F) \subset \mathbb{R}^m \times \{0\}$ and $h_1(F) \subset \{0\} \times \mathbb{R}^m$.

Direct calculations show that the following homotopy is monotonic

$$h_t(x) = \left(h_0(x)\cdot \cos\tfrac{\pi\cdot t}{2}\,,\ h_1(x)\cdot \sin\tfrac{\pi\cdot t}{2}\right). \qquad \square$$

This homotopy was discovered by Ralph Alexander [see 213]. It has number of applications, one of the most beautiful is the given by Károly Bezdek and Robert Connelly in their proof of Kneser–Poulsen and Klee–Wagon conjectures in the two-dimensional case [see 214].

The dimension $2{\cdot}m$ is optimal; that is, for any positive integer m, there are two maps $h_0, h_1\colon F \to \mathbb{R}^m$ which cannot be connected by a monotonic homotopy $h_t\colon F \to \mathbb{R}^{2\cdot m-1}$. The latter was shown by Maria Belk and Robert Connelly in [215]

Cube. Consider the cube $[-1,1]^m \subset \mathbb{R}^m$. Any vertex this cube has the form $\boldsymbol{q} = (q_1, q_2, \dots, q_m)$, where $q_i = \pm 1$.

For each vertex $\boldsymbol{q}$, consider the intersection of the corresponding octant with the unit sphere; that is, the set

$$V_{\boldsymbol{q}} = \left\{\, (x_1, x_2, \dots, x_m) \in \mathbb{S}^{m-1} \,\middle|\, q_i{\cdot}x_i \geqslant 0 \text{ for each } i \,\right\}.$$

Consider the set $\mathcal{A} \subset \mathbb{S}^{m-1}$ formed by the union of all the sets $V_{\boldsymbol{q}}$ for black $\boldsymbol{q}$. Note that

$$\mathrm{vol}_{m-1}\mathcal{A} = \tfrac{1}{2}\cdot \mathrm{vol}_{m-1}\mathbb{S}^{m-1}.$$

By isoperimetric inequality for $\mathbb{S}^m$.

$$\mathrm{vol}_{m-2}\,\partial\mathcal{A} \geqslant \mathrm{vol}_{m-2}\mathbb{S}^{m-2}.$$

It remains to observe that

$$\mathrm{vol}_{m-2}\,\partial\mathcal{A} = \tfrac{k}{2^{m-1}}\cdot \mathrm{vol}_{m-2}\mathbb{S}^{m-2},$$

where k is the number of edges of the cube with one end black and the other in white. □

The problem was suggested by Greg Kuperberg.

Geodesic loop. Assume such loop exists; denote it by γ and let v be its base vertex.

Denote by ξ and ζ the directions of exit and the entrance of the loop. Let α be the angle between ξ and ζ measured in the tangent cone to the surface of cube at v.

Note that $\alpha = \frac{\pi}{2}$. It can be seen from the Gauss–Bonnet formula since each vertex of the cube has curvature $\frac{\pi}{2}$. Alternatively, it can be proved by the unfolding of γ on the plane.

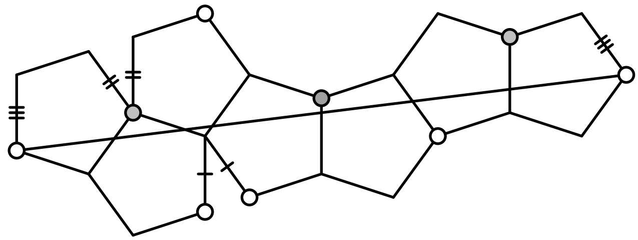
It follows that there is a rotational symmetry of cube with order 3 which fix v and sends ξ to ζ. The later leads to a contradiction. □

The same idea can be used to solve the following harder problems.

📖 *Show the same for the surface of higher dimensional cube.*

Show the same for the surface tetrahedron, octahedron and icosahedron.

For the dodecahedron such loop exists; its development shown on the diagram. The vertices of a cube inscribed in the dodecahedron are circled.



The problem suggested by Jarosław Kędra.

Right and acute triangles. Denote by K the convex hull of $\{x_1,\dots\\ \dots,x_n\}$. Without loss of generality we can assume that K is m-dimensional. Note that for any distinct points x_i and x_j and any interior point z in K we have

$$(*)\qquad \measuredangle[x_i\,{}^{x_j}_{z}] < \tfrac{\pi}{2}.$$

Indeed, if $(*)$ does not hold, then $\langle x_j - x_i, z - x_i\rangle < 0$. Since $z \in K$ we have $\langle x_j - x_i, x_k - x_i\rangle < 0$ for some vertex x_k. That is, $\measuredangle[x_i\,{}^{x_j}_{x_k}] < \tfrac{\pi}{2}$, a contradiction.

Denote by h_i the homothety with center at x_i and coefficient $\tfrac{1}{2}$. Set $K_i = h_i(K)$.

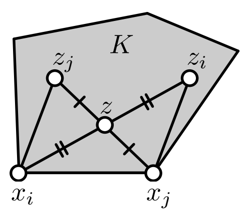
Let us show that K_i and K_j have no common interior points. Assume contrary; that is,

$$z = h_i(z_i) = h_j(z_j);$$

for some interior points z_i and z_j in K. Note that

$$\measuredangle[x_i\,{}^{x_j}_{z_i}] + \measuredangle[x_j\,{}^{x_i}_{z_j}] = \pi,$$

which contradicts $(*)$.



Note that $K_i \subset K$ for any i; it follows that

$$\begin{aligned}\tfrac{n}{2^m}\cdot \operatorname{vol} K = \sum_{i=1}^{n} \operatorname{vol} K_i \leqslant\\ \leqslant \operatorname{vol} K.\end{aligned}$$

Hence the result follows. $\square$

The problem was posted by Paul Erdős and solved by Ludwig Danzer and Branko Grünbaum [see 216, 217].

Grigori Perelman noticed that the same proof works for a similar problem for Alexandrov space [see 218]; the later led to interesting connections to the crystallographic groups [see 219].

The upper bound for the number of points with only acute triangles grows exponentially with m; the later was shown by Paul Erdős and Zoltán Füredi in [220]; the proof use so called *probabilistic method.*

Right-angled polyhedron. Let P be a right-angled hyperbolic polyhedron of dimension m. Note that P is simple; that is, exactly m facets meet at each vertex of P.

From the projective model of hyperbolic plane, one can see that for any simple compact hyperbolic polyhedron there is a simple Euclidean polyhedron with the same combinatorics. In particular Dehn–Sommerville equations hold for P.

Denote by $(f_0, f_1, \dots f_m)$ and $(h_0, h_1, \dots h_m)$ the f- and h-vectors of P. Recall that $h_i \geqslant 0$ for any i and $h_0 = h_m = 1$. By Dehn–Sommerville equations, we get

$$(*) \qquad f_2 > \tfrac{m-2}{4} \cdot f_1.$$

Since P is hyperbolic, each 2-dimensional face of P has at least 5 sides. It follows that

$$f_2 \leqslant \tfrac{m-1}{5} \cdot f_1.$$

The latter contradicts $(*)$ for $m \geqslant 6$. $\square$

The proof above is the core of proof of nonexistence of compact hyperbolic Coxeter's polyhedra of large dimensions given by Ernest Vinberg [see 221, 222].

Playing a bit more with the same inequalities, one gets nonexistence of right-angled hyperbolic polyhedra, in all dimensions starting from 5. In 4-dimensional case, an example of a bounded right-angled hyperbolic polyhedron can be found among regular *120-cells* — the 4-dimensional brothers of dodecahedra.
